Dr. NEUMAN. I think everyone will admit to uncertainty, and I would be the last one to say that we are certain of these figures. I stated 8 as the best number and estimated the range of 4 to 16, in terms of the variability in results reported thus far. There may be something basically very wrong with the results on final equilibrium factors, in which case our models are wrong. There may, indeed, be another factor of perhaps as much as 2 either way. If we multiply 16 by 2, we are up to 32. I think the uncertainty over how soon equilibrium is achieved means that the higher relation found in the survey data is not really in disagreement with the experimentally determined discrimination factors.

I would like also to say that I felt the best model to use is natural strontium, something with which we truly are in equilibrium. However, I feel the data are much less certain than some of our experimental data with isotopes, because I have distrust of emission spectro-

scopy as applied to a wide variety of samples and the difficulty of estimating what is actually the average diet.

I think there is an important document that received no attention (but it is in the record) submitted by Norman McDonald, of UCLA, comparing his best estimate of the Sr/Ca ratio of average diet and of human bone, determining natural strontium by suspected emission spectroscopy. He came out with an estimate of the equilibrium discrimination factor as 15. This is right in between my estimate of 8 and some of the higher estimates from the survey data. (See p. 720.)

So I will confess to this uncertainty, and I think, for purposes of calculation, that we should take them at several levels. I would suggest 8 be considered one reasonable value, and 32. Well, that's too high. I would say 16, right now, is not an unreasonable guess. It might also be 4.

Would you agree, Dr. Libby?

Dr. LIBBY. I think so. If you have to pick a best number, something like that (8 or 16) might be the best one.

Senator ANDERSON. Dr. Langham, I wonder if you would like to run through that table now of the calculations showing strontium 90 in the bone in relation to maximum permissible concentration?

Dr. LANGHAM. This is a repeat of numbers in essence that were placed before you last week. What it amounts to is taking the various estimates of present levels in the bone, or present levels in the soil, and applying ecological discrimination factors, and estimating what the equilibrium level will be when our entire environment is in equilibrium with the present test rates, assuming 10 megatons of fission yield per year injected into the biosphere.

All this amounts to is taking the various estimates of present bone and soil levels and applying Dr. Libby's factor of 8, which is about what these levels will be increased by when equilibrium is reached, assuming that we can continue to test at 10 megatons fission yield per year.

First, we can take Dr. Libby's estimate given in his recent speech, in which he estimated that the United States or rather the north temperature population belt, would reach equilibrium bone levels of somewhere between 5 and 20 sunshine units. These values were derived by assuming different ecological discrimination factors: 1 in the region that Dr. Neuman is talking about, and 1 in the region which Dr. Libby has talked about on occasion, up around 80.

If we take Dr. Kulp's estimate of two for the equilibrium bone level assuming no more tests, which, of course, is for the general population of the latitudinal belt, and multiply it by 8, we obtain an equilibrium bone level of 16 for continued testing at the present rate.

I have taken Kulp's bone data and applied certain corrections that I think refine it to some degree.

Mr. HOLLISTER. At the present rate of testing, and assuming the rate continues, or at the present rate of testing, assuming no more testing?

Dr. LANGHAM. These are numbers assuming we continue to test at the equivalent of 10 megatons of fission products injected into the biosphere per year until we reach equilibrium. This is until the decay of strontium is equal to the amount we are putting up.

So we have 5 to 20 sunshine units by Dr. Libby. Dr. Kulp's numbers give 16.

Our numbers from Dr. Kulp's bone data is 25.

Mr. Eisenbud, in this meeting, estimated about 40 from New York milk data.

My estimate on the basis of other milk data gives an equilibrium bone level of 29.

If we take the soil data, which is the 22 millicuries per square mile that Dr. Libby has estimated at present, multiply by 1.8 to give sunshine units in the soil and apply a discrimination factor of 10 in going from soil to bone, we come out with 42.

Now, Dr. Machta's numbers that he just quoted are handled in this fashion. That is, we take the soil numbers he gave, multiply them by about 2 (1.8 to be exact) to get them to sunshine units in the soil, and then take one-tenth of that, assuming a discrimination factor of 10, and we come out with an estimate of from 70 to 170 sunshine units ($\mu\mu c$ Sr–90/g bone Ca) as the equilibrium bone level that will be reached if biospheric contamination continues at the present rate.

Mr. HOLLISTER. Which soil data are you taking now?

Dr. LANGHAM. The ones Dr. Machta just gave as the equilibrium level with continued testing (350–850mc/mi^2). Is that not right?

Dr. MACHTA. Yes.

Dr. LANGHAM. The ones he just gave would predict, then, for the United States on this basis, assuming a discrimination factor of 10, 70 to 170 sunshine units in bone at equilibrium.

Now the maximum permissible level that we have been talking about is 100 of these units. So I think you can see that at the present rate of testing, if we assume all numbers other than Dr. Machta's are correct, the average is a factor of 3 below what we have accepted as a maximum permissible level, meaning that we can assume that some people will be 3 times the average value, and still not exceed what we have set as a maximum permissible level.

If we take Dr. Machta's number of 70 sunshine units which is his best or average number—is it not—for this?

Senator ANDERSON. The lowest number.

Dr. LANGHAM. The lowest number. Then our present test rates would not allow a factor of three safety. If we take his most pessimistic guess, then our present test rates could not be permitted.

Senator ANDERSON. Actually, Dr. Neuman's testimony of 2.2 megatons of fission products to be somewhat safe—I hope I do not misstate you, Doctor—would indicate also we would be a little bit above what he regarded as a safe level. I should not have said it. Maybe you should.

Dr. NEUMAN. I made two calculations, one using the MPC of 50, and one using the MPC of 100. Using the 100 value, I came out with a maximum equilibrium test rate of 4.4 megatons of fission products injected annually into the stratosphere. But in that calculation I assumed Campbell's model, and 20 percent overall decay due to the reservoir, and I used a factor only of 2 to take care of the variation in individuals, but I used a factor of 3 for nonuniformity.

So, in a sense, my calculation really anticipated Dr. Machta's, although I did not know I was anticipating it at the time I made it.

Senator ANDERSON. It is very interesting that the two worked out as they did. Mr. Hollister.

Mr. HOLLISTER. I would like to introduce for the record an article by Dr. Charles I. Campbell, entitled "Radiostrontium Fallout from Continuing Nuclear Tests."

(The matter referred to is as follows:)

[Reprinted from Science, vol. 124, November 2, 1956]

RADIOSTRONTIUM FALLOUT FROM CONTINUING NUCLEAR TESTS

In spite of widespread comment on the problem of the fallout of radiostrontium from testing thermonuclear weapons, confusion persists in the public mind and perhaps among many of the readers of Science as well regarding the relationship of Sr–90 accumulation on the ground to such factors as assumed mean storage time in the stratosphere and the rate of testing of thermonuclear weapons. Libby's recently published report on the AEC's studies of the Sr–90 problem (1) was not addressed to the effects of continuing weapons tests. Yet his conclusions have recently been quoted in the press as if they were valid if tests continue provided only that test rates remain unchanged.

Libby's analysis considered essentially the question whether nuclear weapons tests to date may have committed us already to an intolerable accumulation of Sr–90. Happily they have not. Speaking to that point, the meteorologists on the National Academy of Sciences study of the biological effects of atomic radiation stated, "At present, the amount of Sr–90 in the stratosphere from nuclear weapon tests is far too small to approach maximum permissible concentration even if it all were to be deposited now. However, if the testing programs of the several countries producing thermonuclear weapons were to intensify, stratospheric storage time may become a critical item in terms of hazard to mankind. For this reason, a continuing program to investigate this phenomenon is needed, including actual measurements of the radioactivity in the stratosphere and improved and more representative methods of observing fallout" (2, p. 60).

The consequences of continued tests can be discussed in terms of a simple mathematical model which is generally accepted by Libby and others in this country as well as in England (3). Assume that Sr–90 is introduced at a constant rate n into the stratosphere, where it is immediately mixed uniformly over the entire glode. According to British data, mixing is evidently reasonably rapid (3, p. 11). Assume further that fallout occurs at a rate $R=kQ$, where Q is the instantaneous stratosphere storage and k is the reciprocal of the mean stratospheric storage time.

Accumulated radiostrontium on the ground, M, can then be shown to be

$$M=\frac{n}{\lambda}\left[\frac{k}{k+\lambda}+\frac{\lambda}{k+\lambda}e^{-(k+\lambda)t}-e^{-\lambda t}\right] \qquad (1)$$

where λ is the radioactive decay constant of radiostrontium. If the constants are expressed in years and the rate of testing is expressed in terms of millicuries of Sr–90 per square mile of the earth's surface introduced per year into the stratosphere, M is given in terms of millicures of Sr–90 per square mile at t years. When $t=\infty$

$$M_{max}=\frac{nk}{\lambda(k+\lambda)} \qquad (2)$$

and the maximum accumulation of fallout is seen to be proportional to the test rate.

Using Libby's best estimate for the mean stratospheric storage time of 10 years and a conservative estimate of the test rate corresponding to the introducion of 2.5 mc/mi^2 yr, per year as a reasonable value for n, the maximum accumulation of radiostrontium would be about 80 mc/mi^2. Libby, *considering only the Sr–90 produced up to 1955*, predicted maximum fallout of less than one-tenth this amount. The two figures should not be confused.

It is not yet known what fraction of the total radiostrontium produced from a thermonuclear weapon reaches the stratosphere and becomes involved in the fallout process discussed here. For this reason, we do not know how to interpret available data on test rates and accumulation of Sr–90—for example, whether little has reached the stratosphere and has subsequently fallen out again relatively quickly or whether much has entered the stratosphere but has been held back by a long storage time. It cannot be said with much confidence, therefore, what rate of weapons testing would result in a given accumulation of Sr–90.

Assuming a 10-year storage time and a continuing test rate about twice that mentioned in a previous paragraph (corresponding to estimates made by Stewart, Crooks, and Fisher in the United Kingdom), the Sr–90 accumulated on the ground after about 35 years would be 80 mc/mi². This would correspond to about 0.14 MPC (maximum permissible concentration) unit in the soil. According to Libby (4), Sr–90 levels in soils are converted to levels in bones of young children at about 70 percent efficiency. This reduces the figure for levels in young children after 35 years of continuous tests to about one-tenth the permissible levels as established for *occupational* exposures. The concentration would not fall much below 0.07 MPC unit even if storage time were found to be 20 years instead of 10. Recently committees of the National Academy of Sciences (2, p. 39) and the British Medical Research Council (5, par. 281) have expressed their belief that only 0.1 MPC unit or less should be permitted for the population at large. In fact, the British report stated (5, par. 360): "So far as radioactive fallout may affect the individual, we believe that immediate consideration would be required if the concentration of radioactive strontium in bone showed signs of rising greatly beyound that corresponding to one-hundredth of the maximum permissible occupational concentration." The rate of introduction of Sr–90 into the stratosphere assumed here is close to that estimated by Libby for the past 3 years. On the assumptions made here, therefore, a long-term test program could conceivably reach or exceed the levels of Sr–90 considered safe for the whole population.

There is little reason to hope that what may be learned about storage time, *k*, will change this situation much. We must hope that new information may allow us to increase the maximum permissible concentration of radiostrontium in the bodies of the people of the world, that means may be found to decrease the input of Sr–90 to the stratosphere from tests, or, preferably, that a new attitude among the people of the world will permit us to lower the test rate, *n*.

CHARLES I. CAMPBELL,
Route 4, Box 361–M, Vienna, Va.

Mr. HOLLISTER. I would like to read a paragraph from Dr. Libby's speech before the American Physical Society on April 26, 1957. This is on page 23, the third paragraph.

Of course, as testing continues and more fallout occurs, the levels will rise. The strontium 90 that still resides in the stratosphere at the present will fall out according to our expectations at a rate which just about compensates for the decay of the material already deposited, so that no great additional increase from this source is to be expected from weapons fired in the past. If this testing should continue at about the same rate as it has averaged over the last 5 years, then we should at equilibrium, after an infinite time, approach a level of 8 times the present rate, since the average life of strontium 90 is 40 years. This assumes that the future testing will be conducted so as to give in each future 5-year period the same as the last 5 have. And so we would expect in the United States at that time an average human strontium 90 concentration of 20 sunshine units with the conservative factor of 20 between the topsoil concentration and the concentration in human bone, or 5 sunshine units if the factor of 80 is used. In other words, in the United States something between 5 and 20 sunshine units would be the equilibrium concentration of human bones if testing continued

indefinitely at the average rate of the past 5 years. This level would be approached only after a few decades. After 28 years the level would be half of this equilibrium value, and after another 28 years, 56 years total, from an arbitrary beginning which we have set as 1952, we would expect in the year 2008 three-fourths of the equilibrium figures. So somewhere between 4 and 15 sunshine units of strontium 90 in human bones in the United States might result from the present type of testing being continued for the next 50 years.

I would like to ask Dr. Libby how he derived the factor of 8 that would represent the levels at equilibrium as compared with the levels now.

Dr. LIBBY. Mr. Hollister, as you probably know, the strict derivation of this is somewhat complicated mathematically. But let me try to express it in words.

If you take a rate of testing which is equal to the average over the last 5 years, then per year you have got one-fifth of the total we have now.

Now, if you continue this indefinitely, you will accumulate a final total amount which is equal to the average lifetime of the radioactive strontium.

The average lifetime of radioactive strontium is 40 years, not 28 years. Twenty-eight years is the halflife. So the calculation is after an infinite length of time you will have 40 years' worth if no strontium decays.

The reason that you do not get more than 40 years' worth is that the decay of the strontium compensates for the new accumulation. Now, this holds for both stratosphere and for the stuff that is on the ground.

Now, actually the calculation is not strictly rigorous, in that, as Dr. Machta pointed out, and as I have pointed out, too, the strict and rigorous calculation is a bit more complicated. But, considering all of the factors that are involved here, and restricting the consideration to the United States, which was the condition of that paragraph—I am not sure that paragraph made that clear. We were talking about the United States——

Mr. HOLLISTER. I think it would be implied in the sentence that, "So we would expect the United States," et cetera.

Dr. LIBBY. Yes. I consider that this factor of 8 is good enough and a good-enough approximation to the truth to give. The exact truth is not known to us.

We do not know, for example, whether after a long time the strontium 90 that lies in the soil will not act in the way that calcium acts, in that a portion of it will become unavailable to the plant. We do not know whether the strontium 90 that has been there for 5 or 10 years may not be less available to contaminate plants. Chemically, it is quite likely that this will happen. I had in mind, in using this factor of 8, to load the calculation a little bit for these factors which we have not yet known. I was trying to get a number which I think is the solidest number.

Mr. HOLLISTER. You would agree, then, it is a loaded number?

Dr. LIBBY. It is loaded on the side of truth, in the side of actuality, in the direction of what is most likely to happen.

Now, it is very difficult to estimate the effect of this precipitation out, or removal from the biosphere of fallout strontium, which I think we will discover, and I already see evidence in our actual data.

Mr. HOLLISTER. Would you agree that the Campbell model is correct?

Dr. LIBBY. The Campbell model is strictly correct on the assumptions made, surely. I believe it is. I have not gone through all of the derivations in detail.

Mr. HOLLISTER. I went through the Campbell model in trying to justify this factor of 8, and using a half life of strontium 90 of 28 years, the only way I could justify this factor of 8, 8 now being the ratio of the level on the ground at infinite time, and the ratio now being 5 years after we started the constant rate of testing——

Dr. LIBBY. Right.

Mr. HOLLISTER. The only way I could justify this factor of 8 was to assume the storage time as zero.

Dr. LIBBY. That is strictly mathematically correct.

Mr. HOLLISTER. If I assume the storage time is 10 years, which I believe is sort of an average number that we have seen in the literature, this factor of 8 becomes a factor of 32 or 33.

Dr. LIBBY. That is certainly wrong. Not that your calculation is not right, Mr. Hollister, but for the reasons I have pointed out. You see, we now have on the ground about—what is it—two times as much as we have in the stratosphere, something like that, in the United States. And this is a very important consideration in your calculation. I cannot do it in my head and get the strict mathematical number. But we have to consider the biological aging of the strontium that goes into the soil. It is very difficult to know exactly what to do with this, but is seems to me that it was a reasonable thing to do to say that this aging out was about compensated for by the stratospheric—the fact that the stuff is stored in the stratosphere.

Mr. HOLLISTER. Would you say then that one of the problems here is the Campbell model is not strictly applicable?

Dr. LIBBY. Well, I would not put it quite that way. I would say that we do not know enough to make this calculation with complete certainty. But I do believe that the numbers given in the first row (on the blackboard) are just about right, and that the schedule that will be attained, that is, half of it by 1985, is just about right.

Mr. HOLLISTER. You would agree, though, that if, somehow in this loaded calculation we loaded it wrong, it is possible by virtue of the Campbell model argument that that 5 to 20 could be greater?

Dr. LIBBY. I think this is very unlikely. You see Dr. Campbell did not consider the aging, the removal of the strontium 90 from the biosphere. I believe that is certain to be an appreciable effect. But we do not know enough yet to know how important it is.

Mr. HOLLISTER. Would the others like to comment either on this discussion or on the numbers?

Dr. NEUMAN. I would like to say one thing. If the Campbell model is 32, this is a factor of 4, and yet you said earlier, Dr. Libby, you thought the aging was only a factor of 2. We still have a factor of 2 running loose.

Dr. LIBBY. I cannot check in my head the factor of 32 of Mr. Hollister. I do not distrust Mr. Hollister's figure, though.

Dr. MACHTA. My numbers on the board obviously stick out like a sore thumb. The reason lies partly in the factor of 8 used to increase the other values. The aging factor that Dr. Libby just indicated as

being included in the 8—when you put that in my figures, they would be reduced to the same order of magnitude as the others. So those numbers are not comparable. If you do not take into account Libby's aging factors, and if you make the assumption, for example, that half of what fell out in the United States is tropospheric, and half stratospheric, then instead of a factor of 8 you get something like 14 for the conversion of the 5-year fallout to equilibrium fallout.

Further, if you assume what came out of Castle is only 3 years old instead of 5 years old, the number 114, becomes even higher.

So this is the reason for the difference. Dr. Libby has incorporated in the 8 other factors. These and other differences should be included in the 70 and 170, and the changes will bring my answers down to the others. So as now written they are not comparable and I do not wish the record to show this comparison.

Dr. LIBBY. Should they not be still higher?

Dr. MACHTA. No, I do not think the answers will come out higher if you take into account the aging and other factors.

Mr. HOLLISTER. Do we not all agree on the discrimination factors? So there is only the question of uniformity and nonuniformity, and the upper limit would have to be higher; isn't that so.

Dr. MACHTA. The upper limit, yes.

Senator ANDERSON. I am going to recognize Mr. Durham in just a second.

Would you submit a subsequent calculation for our record that might take into consideration some of these other things? We are trying to find where the truth lies. There are all kinds of truths: There are truths, half-truths, the whole truth and nothing but the truth, so help you God.

Dr. MACHTA. I have given the amount falling on the ground. When that is converted to what goes into the bone, others are contributing, what are the conversion factors? If someone would tell me, then the numbers can be made comparable. But this has not been done, sir.

Senator ANDERSON. I just thought you might say, assuming a certain factor, which everybody seems to agree on, 8 or some other figure, is proper, your figures would come to this point. If you can do it, fine, we will appreciate it. We have appreciated your cooperation thus far so much. If you can do it, fine. If you cannot, nobody is going to put you in the penitentiary.

Mr. Durham.

Chairman DURHAM. My question may be irrelevant, but I am going to ask it anyway. Is it in general agreed by all the scientists worldwide that no strontium existed until we developed a thermonuclear weapon?

Representative COLE. How can you be sure? I am intrigued by the question, because I am curious to know.

Chairman DURHAM. I was thinking of the possibility. Of course, this is getting rather high into the problems above the stratosphere and biosphere and all the rest of the spheres, and getting up into the satellites. Is there any scientific data on the possibility this could have happened over the many, many years of existence of the satellites that some chemical reaction possibly took place, and now we are getting this down on the earth?

Dr. LIBBY. You asked two questions, Mr. Durham.

To answer the first one, well, you stated, and Mr. Cole asked if you knew your statement to be correct.

Representative COLE. No. You misunderstood. You gentlemen were nodding your heads when Mr. Durham asked if there were general agreement worldwide among the scientists that strontium 90 did not exist prior to the atomic age. You were all nodding your heads. It was because of that that I said, "How can you be sure?"

Dr. LIBBY. Yes. I will tell you.

Representative COLE. Referring to strontium 90.

Dr. LIBBY. I will tell you how we can be sure. We looked for it before the atomic bomb was invented, and we could not find it, sir. That is how we know and we can still look for it by taking old material. As a matter of fact, the other day I got a can of old tuna fish from a neighbor of mine, which was canned before July 16, 1945, and we will look for strontium 90 in that. Dr. Langham has been collecting milk samples. I do not know whether he has been successful. But just to be sure that there was no strontium 90 before the atomic bomb was first fired we have done these things.

We have looked in old bodies and there is not any. We have looked in the ground below this 2½-inch level and there is not any. This is how we know, Mr. Cole.

Chairman DURHAM. How high have you looked for it?

Dr. LIBBY. Well, sir, the highest we can look is as high as we can sample air, which is—I do not know the exact answer, but it is a few miles.

Chairman DURHAM. Will we get any data from the satellites we are building?

Dr. LIBBY. Now on your satellite question, it is a very interesting point. A few months ago we would all have given a categorical "No" to your question and said there could not be any up there. But recent evidence has indicated that we did not know as much as we thought we knew about the contribution of the sun to the earth. We learned a year ago last Washington's Birthday during the incidence of a great solar flare that matter comes to us from the sun directly, and that the so-called cosmic rays, which we have been speaking about so much, come in part from the sun. Now, if these can come from the sun, I am not so sure that a tiny little negligible amount of strontium 90 might not possibly come from the sun.

The only thing I can say now is that it must not be too large an amount, or we would find it in preatomic bones and soil, and we have not. So it is not too large, but it still might be up there in detectable quantities. I am quite sure it will not be enough to in any way upset our considerations.

Chairman DURHAM. Then we cannot convict man entirely at the present time of placing this burdensome problem upon the world?

Dr. LIBBY. I am not sure that it is there, either, Mr. Durham, but there is a possibility.

Chairman DURHAM. A possibility.

Senator ANDERSON. Off the record.

(Discussion off the record.)

Senator ANDERSON. I think if there is no violent objection, I am going to take advantage of the suggestion here and adjourn. We will not have a session this afternoon because the House is very busy with

a long series of votes, and it makes it most inconvenient for the Members to come and go. They want to be sure to hear it all.

Therefore, tomorrow morning at 10 o'clock, in the old Supreme Court room in the Capitol, the final session will be held. There will be no afternoon session.

That is the final session only as to these hearings.

The chairman of the subcommittee will undoubtedly, I think, recommend to the full committee that the hearings be adjourned at that time for the development of subsequent testimony, if it seems desirable. Is that not correct?

Representative HOLIFIELD. Yes.

Senator ANDERSON. Therefore, we will meet tomorrow morning in the old Supreme Court room, at 10 o'clock, and we will have only a morning session, because some of these witnesses who have been kind enough to stay with us for several days are going to find it necessary to leave, and we want their contributions to us as we we go along.

Mr. Durham.

Chairman DURHAM. I would like to compliment the panel this morning for a fine display of knowledge. I feel it did a lot of good here and throughout the world.

Senator ANDERSON. Just before we go, Dr. Machta, you said your figures stick out like a sore thumb?

Dr. MACHTA. Yes. I do not think they should be put on the board and quoted. They are not comparable because the proper discrimination factors have not been applied. Therefore, I do not believe the press should quote them in any way whatsoever, sir.

Senator ANDERSON. Let us ask the newspapermen present not to report the Machta figures which he desired not to be put on the board. I would not want to take advantage of any witness here. I know Dr. Langham well enough to know that he put them on with the best of intentions, and only to call attention to the fact discrimination factors is not in it.

If a hundred is permissible, and he has a 170 figure, it might look dangerous, which he does not desire to have it look. I am very anxious we do not distort the comments of a very fine scientist who has been willing to come to us and help us in this discussion.

Thank you very much.

(Below are several items of correspondence following the day's discussion and a comprehensive report on the potential hazards of strontium–90 prepared by Dr. Wright Langham and Dr. E. C. Anderson.)

[Telegram]

JUNE 7, 1957.

HAL HOLLISTER,
Joint Committee on Atomic Energy,
The Capitol, Washington, D. C.:

Regret unable to remain for further discussion at Thursday morning panel. In view of importance of question as to whether National Academy of Sciences pathology report is or is not out of date, suggest Joint Committee request answers to following questions from Drs. Warren, Brues, Neuman, Langham. To wit on page 7 of the pathology report it is stated that "there seems no reason to hesitate to allow a universal human strontium burden of one-tenth the (occupational) permissible level." That is, of 100 sunshine units. Further, on page 2–9, it is stated that "it was felt that an amount of internal radiation

sufficient to double the large population background could certainly be considered safe." That is, of approximately 40 sunshine units. On the other hand, the British Medical Council report stated on page 68 that immediate consideration would be required if the strontium concentration in the human bones showed signs of rising greatly beyond 10 sunshine units.

According to some of the testimony presented to the Joint Committee it is a reasonable although unproven inference from available data that a worldwide average strontium 90 level in human bones of 100 sunshine units could be expected to produce several million cases of leukemia and bone cancer over a few decades. In view of these comparisons, do you feel that the existing pathology reports, prepared in early 1956, gives a balance view of the strontium 90 problem and serves as a proper guide for consideration of it?

Dr. WALTER SELOVE.

UNITED STATES ATOMIC ENERGY COMMISSION,
Washington, D. C., June 7, 1957.

Mr. H. L. HOLLISTER,
Staff Member, Joint Committee on Atomic Energy,
Congress of the United States, Washington, D. C.

DEAR MR. HOLLISTER: The point about the factor by which the soil burden of strontium 90 would be expected to increase if testing were to continue at the average rate and in the same type as during the last 5 years was discussed by yesterday's panel, and you asked why I had given the factor to be 8 in my April 26 address before the American Physical Society when this would be strictly true only if the stratospheric residence time were zero.

I told you that the factor of 8 was given because the aging of deposited strontium 90 in the ground would gradually render a considerable portion of it unavailable to plants and that the lower factor of eight was chosen to compensate for this. The aging effect is analogous to the incorporation of the strontium 90 into insoluble solids form which will not feed the plants. For example, calcium occurs in soils in two forms—the "available" and the "unavailable" and the distinction always is made in soil analysis.

The factor of increase in the absence of any aging appears to be about 11 instead of 32 as given yesterday. (The cause of the difference between our calculations is not clear to me. I did not use Dr. Campbell's equations but derived my own as given below. Perhaps some inadvertent error is involved. I would be pleased to check this out with you.)

I believe that the decrease from 11 to 8 to account for about 30 percent of the strontium 90 becoming unavailable to the plants is reasonable.

The detailed calculation is appended.

Very sincerely yours,

W. F. LIBBY.

APPENDIX

Amount of Sr^{90} in the stratosphere after t years is, y.

Amount of Sr^{90} on the ground is, x.

Since the rate of accumulation in the stratosphere, dy/dt, is the deposition rate, S, less the fallout rate, $y/10$, and the decay rate, $y/40$,

$$dy/dt = S - y(1/10 + 1/40), \text{ or}$$

$$y = S\left(\frac{1 - e^{-t(1/10+1/40)}}{1/10 + 1/40}\right).$$

Similarly,

$$x = 40(S+T)(1 - e^{-t/40}) - y.$$

In these equations, T is the rate of tropospheric fallout. In order that at five years the ratio of the amount deposited (30 mc/mi^2 in the northeastern United States) to that in the stratosphere (12 mc/mi^2) be given correctly the ratio of S to T must be 4 to 7. With this the ultimate amount on the ground relative to that deposited at 5 years is 11.

UNIVERSITY OF ROCHESTER,
Rochester, N. Y., June 12, 1957.

Dr. W. F. LIBBY,
Commissioner, United States Atomic Energy Commission,
Constitution Avenue, Washington, D. C.

DEAR DR. LIBBY: Thank you for the copy of your letter of June 7, 1957. My associates and I have gone over the equations and find them to be mathematically correct. I believe I understand the origin of the difference between your number 11 and Hollister's number 32. Hollister, perhaps, will agree. I believe he was using Campbell's equation which is derived for stratospheric fallout only. The number 32 applies to ground levels due to stratospheric fallout only not to the total on the ground at $T=5$ years.

I think, though probably obvious to most, it should be pointed out that predictions of equilibrium from these equations are based on two assumptions: first, that the overall test rate will be constant and second, that the proportion of trapospheric to stratospheric fallout will remain the same.

Is it correct to say you now predict ultimate ground levels of between 432 to 600 sunshine units (depending on the importance of your postulate of ageing) if testing continues? If so, and if you agree with me that the population average should not exceed 40 S. U. (MPC=100 S. U.), then discrimination factors of 10 to 15 would be required for the present test rate to be permissible indefinitely. A figure of 80 percent of the "present test rate" would seem to me to be a "permissible test rate" compatible with your figures.

I would appreciate your comment since my estimate, though only differing by a factor of two (4.4 Megations), presumed ideal conditions of worldwide fallout.

Sincerely yours,

WILLIAM F. NEUMAN,
Associate Professor, Pharmacology and Biochemistry.

cc: Mr. Hal Hollister.

UNITED STATES ATOMIC ENERGY COMMISSION,
Washington, D. C., June 24, 1957.

Prof. WILLIAM F. NEUMAN,
School of Medicine and Dentistry,
The University of Rochester, Rochester 20, N. Y.

DEAR PROFESSOR NEUMAN: You are correct in finding that my equations predict ultimate ground levels of between 400 and 600 S. U. (depending on the importance of the aging factor) if testing were to continue indefinitely. A population average concentration of 40 S. U. then would correspond to discrimination factors of 10 to 15. Of course, these discrimination factors would include the ploughing factor which I mentioned the other day. Of course, one normally does not plough range land but, over a period of many years, I believe that Sr^{90} would gradually mix itself with deeper lying layers of soil. This factor should be included in the overall discrimination factor. I believe in your discussion of discrimination factors, you begin with vegetation and then consider the discrimination factor between vegetation and human bone. Do you not?

I hope we can meet again before long to discuss these problems.

Sincerely yours,

W. F. LIBBY.

cc: Mr. Hal Hollister.

UNITED STATES DEPARTMENT OF COMMERCE,
WEATHER BUREAU,
June 27, 1957.

Hon. CHET HOLIFIELD,
United States House of Representatives,
Washington, D. C.

DEAR MR. HOLIFIELD: In response to a request by Senator Anderson for information on the morning of June 6, 1957, I am enclosing the following remarks for the clarification of my testimony.

The strontium^{90} bone content at equilibrium (i. e., if tests are continued at the current rate of 10 megatons of fission products per year and after a very long time) can be obtained from the predicted fallout. In my testimony, I estimated

that the fallout would lie between the 350 to 850 millicuries per square mile. These numbers were converted to strontium^{90} bone content in sunshine units by Dr. Langham to provide a range from 70 to 170 sunshine units. They were compared with numbers also estimated by Dr. Langham for other investigators which lay between 5 and 40 sunshine units. There are four reasons why the human bone content of strontium^{90} based on my fallout estimates were higher than the others:

1. The conversion from millicuries per square mile to sunshine units in average soil was a factor of 2. It should have been 1.8.
2. The conversion of fallout in 1956 to fallout after equilibrium has been established was performed by Dr. Langham through a multiplication of 8 for the numbers assigned to the other analysts. The factor of 8 should have been somewhat higher. The 8 was used to compensate for the aging of strontium^{90} in the soil and the effects of plowing.
3. Many of the other investigators (and perhaps all) use discrimination factors in converting from soil to human bone which are greater than 10, that is, gave lower bone content from the same soil. The value of 10 was used by Dr. Langham in converting from soil to human bone for my numbers.
4. The upper bound quoted in my fallout figures is offered only as an extreme. Other investigators, except for Mr. Eisenbud, did not offer upper bounds.

A review of the situation during the past several weeks has indicated two features. First, the use of comparable conversion factors yields final answers for my fallout estimates which are essentially the same as those for Dr. Libby and Mr. Eisenbud. I was unable to check the numbers assigned to the other investigators. The reason for the similarity is evident. Both Dr. Libby and Mr. Eisenbud have made their predictions for future fallout based on fallout in northeast United States where there is nonuniformity of fallout. That is, the fallout in northeast United States is over 3 times the worldwide average in 1956. Second, I am unable to provide a set of predictions for human bone content of strontium^{90} at equilibrium if the test rate is continued at about 10 megatons per year, because I cannot choose between the various conversion factors which have been quoted during the fallout hearings. For example, the discrimination factor from soil to bone has been variously estimated as lying between 8 and 80.

I feel that the uncertainty in nonuniform fallout over the globe represents only one of many of the uncertainties in the final prediction of human bone content. Other factors are: The importance of transportation of food from one area to another, the variability of calcium content of soil, the relative importance of plowing and aging, variability among people, etc. It would seem to me that some kind of a statistical treatment is necessary. The use of extremes of each of these factors does not obtain a realistic upper bound for the likely bone content of human beings.

In conclusion, I should like to repeat that the estimate of 850 millicuries per square mile, the equilibrium fallout if test rate is continued at 10 megatons per year, is offered only to show that even with the uncertainty in meteorological factors, a reasonable upper bound can be provided. It is a guess which we hope will be refined in the next few months.

Sincerely yours,

LESTER MACHTA,
Chief, Special Projects Section, Office of Meteorological Research.

UNIVERSITY OF ROCHESTER,
Rochester, N. Y., July 2, 1957.

Dr. W. F. LIBBY,
Commissioner, United States Atomic Energy Commission,
Constitution Avenue, Washington, D. C.

DEAR DR. LIBBY: This letter has as its purpose the possible resolution of some of the differences in the various calculations presented at the congressional hearings. I understand from Dr. Potts that an attempt is being made to recall at least some of the participants of the roundtable discussion for this same purpose.

Unless I am mistaken, Machta and I derived independent approaches to the problem. Eisenbud, Kulp, Langham, and you gave independent calculations of bone levels, but all of these were based on your predictions of ground levels at full equilibrium.

Machta and I were, I believe, in substantial agreement provided we used similar discrimination factors. All the values based on your ground-level estimates, however, were somewhat lower and the question is "Why?"

I have, to my own satisfaction, answered this question. Using your equations as given in your letter of June 7 to Mr. Hollister, I have substituted in the same values with one exception: I used $t=3$ years for stratospheric fallout and $t=5$ years for tropospheric fallout. After all, there was inappreciable stratospheric fallout prior to test Castle. On this basis, $T=6$ mc/mi^2/yr. and $S=4.8$ mc/mi^2/yr. and x, at $t=\infty$, is 396 mc/mi^2, or about 710 sunshine units. Using as I did an overall discrimination of 8, equilibrium bone values would then average 89 sunshine units which is 2.2 times too high (MPC=100, av.=40).

The so-called present "level of testing," said to be 10 megatons per year, should thus be reduced, on these assumptions, to about 4.5 megatons. This agrees with my testimony giving the figure of 4.4 megatons per year, whether we base our predictions on rate equations or on a presumed equilibrium. This is true, of course, only if you find my application of your equations to be acceptable. If you do agree, then, the equilibrium values of Eisenbud, Kulp, and Langham should be multiplied by 13.2/8, before they are corrected for "aging," "plowing," etc.

You asked (June 24) whether the discrimination factor of 8 covered only the area from vegetation to bone. In my testimony, I specified this to be the case. I said further that other more or less favorable factors (fallout to vegetation) may soon be discovered, but the experimental data were, in my opinion, as yet too inadequate to permit the assignment of numerical values. I then asked for further discussion of this point. In summary, then, I used 8 as an overall factor, but it admittedly is based only on the transfer from vegetation to bone.

Your comments will be appreciated.

Very truly yours,

WILLIAM F. NEUMAN,
Associate Professor, Pharmacology and Biochemistry.

Division of Biology and Medicine,
Dr. C. L. DUNHAM,
Atomic Energy Commission, Washington, D. C.

DEAR MR. DUNHAM: Thank you for your letter regarding the July 29 symposium. It is very fine that the unfinished business of the congressional hearings is being pursued by the Commission.

In addition to the problem of prediction of future levels of strontium #90, I wonder whether the plans for the meeting include discussion of the "permissible level" of strontium #90 in humans. This subject also was not fully covered in the hearings. Because of its great importance, discussion of this subject should be carried out to a more satisfactory stopping point.

Sincerely yours,

WALTER SELOVE.

cc: H. Hollister.

POTENTIAL HAZARD OF WORLD-WIDE Sr^{90} FALLOUT FROM WEAPONS TESTING

By Wright H. Langham and Ernest C. Anderson

Los Alamos Scientific Laboratory, University of California,
Los Alamos, New Mexico

1. INTRODUCTION

During the past year public attention has been increasingly focused on the potential hazard to the general population of wide-spread, low-level, radioactive fallout from nuclear weapons testing (1–5). Although a number of radioisotopes are present in the fission mixture, Sr^{90} is the major concern. It is believed to be the most important radionuclide because of its similarity to calcium, long physical and biological half-life, and high relative fission yield. These factors

lead to high incorporation in the biosphere and a long residence time in bone. General contamination will result in the bones of the population eventually reaching an equilibrium state with Sr^{90} in the biosphere. The predominance of Sr^{90} over other long-lived radioelements as a potential hazard can be deduced in part from data in Table I, which show that it is the only isotope that combines high fission yield, long half-life, high absorption rate and a low maximum permissible level (MPL). These data suggest Cs^{137} by at least an order of magnitude fission product, and its presence in people and foodstuffs has been reported (6, 7). However, for reasons not discussed here, its potential hazard to the population is believed to be less than that of Sr^{90} by at least an order of magnitude (8).

TABLE I.—*Radioelements of importance to long-term fallout problem*

Radioelement	Type radiation	Fission abundance [1]	Radiological half-life	Absorption on ingestion	MPL (μc)
		Percent		*Percent*	
Pu^{239}	α	----------	24,000 years	3×10^{-3}	0.04
Cs^{137}	β,μ	6.2	28 years	100	98
Sr^{90}-Y^{90}	β	5.1	28 years	35	1
Pm^{147}	β	2.6	3.7 years	3×10^{-2}	25
Ru-Rh^{106}	β,μ	.5	1.0 year	5×10^{-2}	4
Ce-Pr^{144}	β,μ	5.3	275 days	3×10^{-2}	1

[1] Slow neutron fission of U^{235}.

Appraisal of the potential hazard from world-wide fallout of Sr^{90} requires consideration of the extent and rate of fallout, its method of incorporation into the biosphere and the human body, present and predicted levels in soils and people, the basis of presently accepted maximum permissible body levels, and the biological significance of present and future body levels in terms of the megatons of fission weapons detonated. Information on all of these factors is somewhat inadequate at the present time. This paper is an attempt to present a general summary of the present thinking with regard to the above factors.

2. GENERAL WORLD-WIDE FALLOUT FROM BOMB TESTING OPERATIONS

Based on measurements of world-wide fallout, Libby (2, 3) proposed a mechanism by which atomic debris is disseminated throughout the world. This theory leads to three kinds of fallout, which are illustrated in Fig. 1. First is local fallout which is deposited in the immediate environs of the explosion during the first few hours. This debris consists of the large particles from the fireball and includes residues from the soil and structures which are swept into the cloud in wholly or partially vaporized state. The fraction of the total radioactivity which falls out locally depends very much on those conditions of firing which govern the amount of soil and extraneous debris incorporated in the fireball.

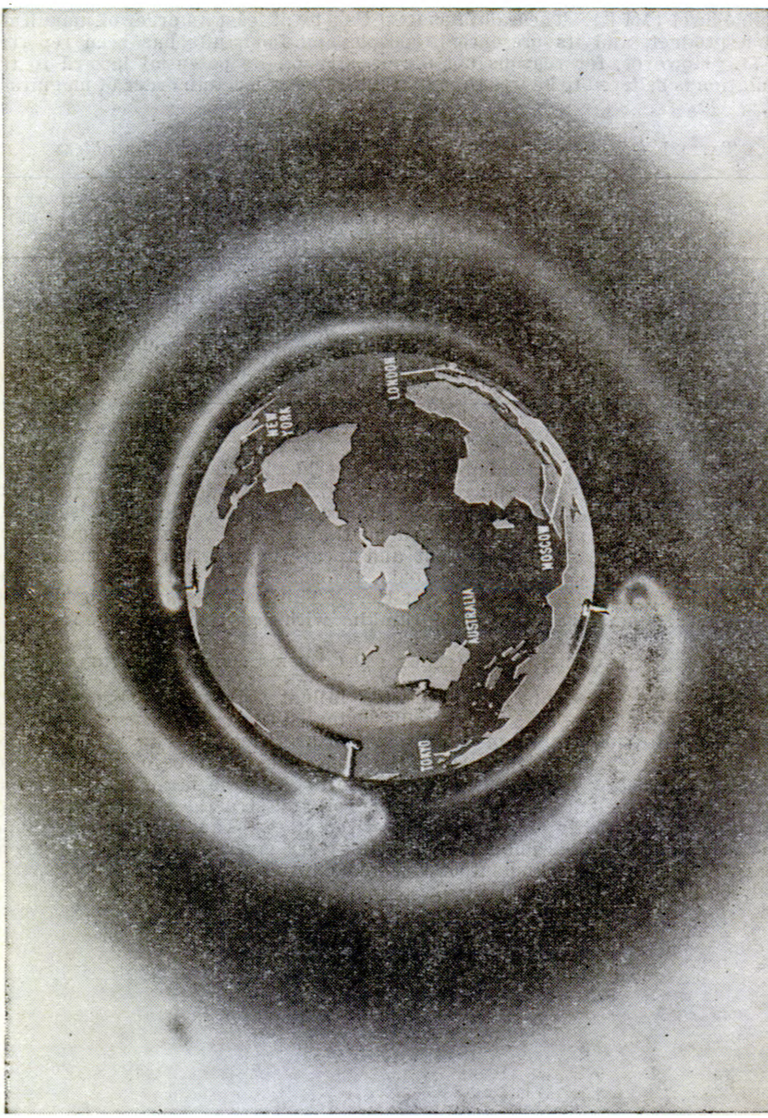

FIG. 1.—Types of radioactive fallout from weapons tests (local, tropospheric and stratospheric).

The second type (stropospheric fallout) consists of that material injected into the atmosphere below the tropopause which is not coarse enough to fall out locally. This debris is sufficiently fine that it travels great distances, circling the earth in the general latitude of the explosion, until removed from the atmosphere by rain, fog, contact with vegetation, and other meteorological and/or physical factors. The average tropospheric fallout time is estimated as 20 to 30 days. The fraction of the fallout which is in this category depends mainly on the size of the explosion and the conditions of firing. If the explosion exceeds a certain minimum size (about one megaton (MT)), the fireball will have enough energy to penetrate the tropopause carrying fission products into the stratosphere. Smaller detonations leave in the troposphere all debris not deposited locally. The fraction of the fission products from a large weapon that remains in the tropopause depends on the size of the explosion, conditions o' firing, and meteorological factors.

The third type (stratospheric fallout) is composed of fission products that are carried above the tropopause and can result only from large weapons. Libby (3) has postulated that the activity is mixed rapidly throughout the stratosphere and falls back uniformly into the troposphere (see footnote page 10), where it is deposited over the earth's surface in relation to meteorological conditions. The over-all mean deposition time is estimated at from 6 to 10 years.

The above mechanism leads to a general distribution pattern of radioactivity over the surface of the earth as shown in Fig. 2. Libby's estimates (3) of Sr^{90} levels in the fall of 1956 suggest 22 mc/mi² for the midwestern section of the United States, 15 to 17 mc/mi² for similar latitudes elsewhere in the world,[1] and 3 to 4 mc/mi² for the rest of the world. The higher value for the upper midwestern United States is attributed to greater local and tropospheric fallout because of the proximity of our own continental test site.[2] The 15 to 17 mc/mi² deposited between about 60° N and 10° N latitude is due to tropospheric fallout from all shots of less than 1 MT conducted in the northern hemisphere plus stratospheric fallout from all weapons greater than 1 MT. Actually, this general picture is greatly oversimplified. Once fission products are suspended in the troposphere (either directly by the detonation or by air exchange, regardless of mechanism, between the troposphere and the stratosphere), meteorological conditions play a major role in their deposition. Libby (3) has stressed the importance of rainfall, fog, and mist. Within any major fallout area one might expect to find fluctuations in the level of surface deposition which correlate with local meteorological conditions. Higher deposition in a local area does not correlate necessarily with total precipitation but rather with frequency of rainfall.

---

[1] The latitude position and width of the north temperate tropospheric fallout belt is variable and hard to estimate. Earlier Libby mentioned 60°N–10°S (2); later he mentioned 50°N–10°N (3); and most recently he referred to 60°N–10°N (10). The area between 60°N–10°N latitude agrees better with soil data and it is assumed by the authors that the 15 to 17 mc/mi² applies to this area.

[2] Machta (47), in testimony given during the Open Hearings of the Joint Committee on Atomic Energy, postulated that stratospheric mixing is slow and that stratospheric distribution of fission products is still nonuniform. He feels that a major portion of the nuclear debris is still in the northern portions of the northern hemisphere, rather than uniformly spread over the entire globe or even uniformly dispersed in the northern hemisphere itself. He feels also that stratospheric movement of the fission products is largely by direct transport from west to east in the general latitude of the point of injection with very slow vertical mixing. Slow polewards circulation of stratospheric air from equatorial regions provides some mixing towards the poles. The higher concentrations of fallout in the temperate latitudes was explained on the basis of air exchange between the troposphere and stratosphere through the break in the tropopause frequently found in the vicinity of the jet stream. A large part of the higher concentration of Sr^{90} found in the northern part of the United States may result from such uneven stratospheric leakage instead of the proximity of the Nevada Test Site. In either case, the general distribution of Sr^{90} is relatively the same qualitatively. Quantitatively, Machta's model predicts a greater degree of nonuniformity of fallout over the earth with higher concentrations in the temperate latitudes.

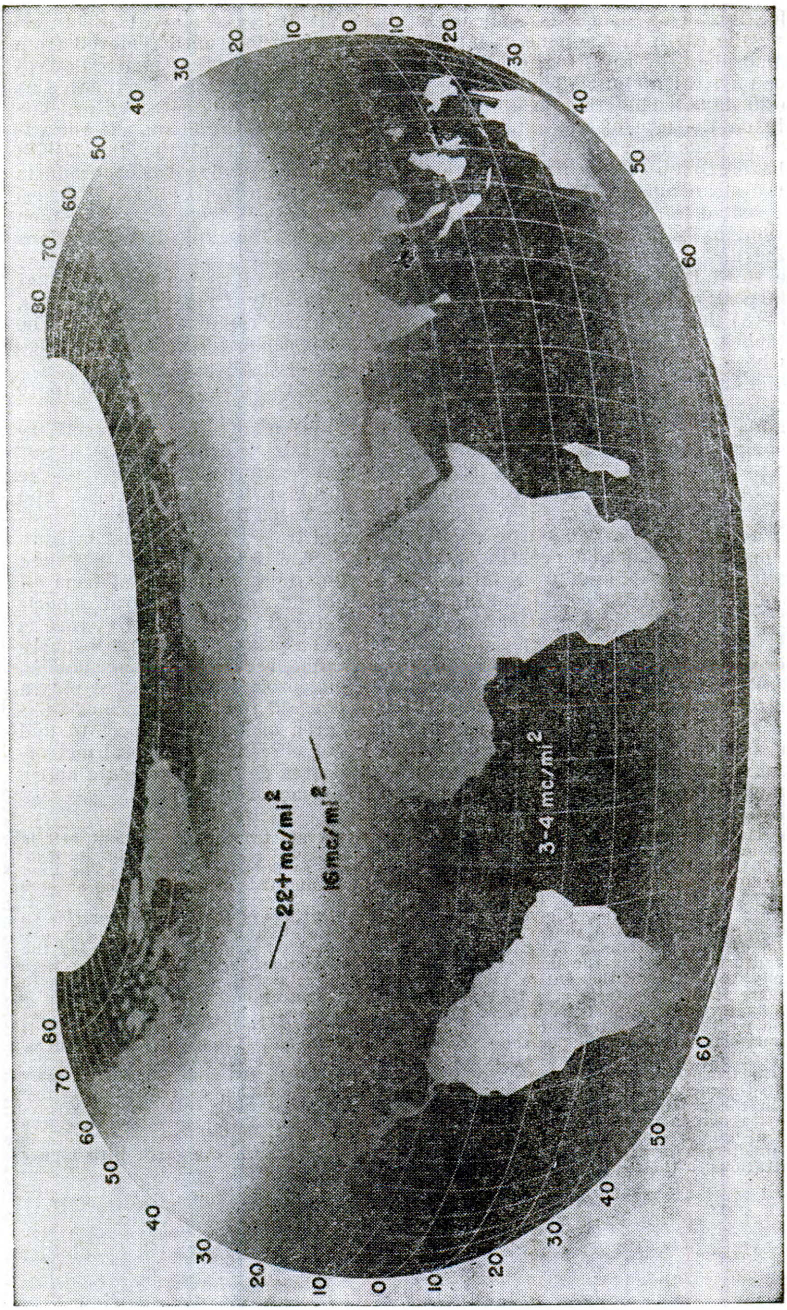

FIGURE 2.—General levels of world-wide fallout deposition.

3. PRESENT AND PREDICTED MAXIMUM LEVELS OF SURFACE DEPOSITION

Libby (3) estimated that the stratospheric reservoir (in the fall of 1956) contained the products of about 24 megatons of fission. One megaton of fission results in the formation of enough Sr^{90} to give a surface deposition of 0.5 mc/mi^2 if uniformly distributed over the entire surface of the earth. If all material presently in the stratospheric reservoir were deposited instantaneously and uniformly over the earth, present values would be increased by 12 mc/mi^2, and the maximum surface deposition of Sr^{90} would result. Maximum deposition, however, will not occur because of the relatively long average stratospheric storage time (6 to 10 years), which will allow some of the strontium to decay before deposition. Figure 3 shows, however, that the predicted maximum level is not highly dependent on the mean time of fallout. Although British investigators (9) appear to favor a fallout half-time of about 5 years, Libby (2) has chosen to use a value of 7, which corresponds to a mean time of about 10 years. With a mean time of 10 years, the maximum predicted level of Sr^{90} surface contamination from fission products alreadmy present should occur in about 1975. Table II shows the estimtaed present levels (October 1956 (3)) and the maximum predicted levels that might be expected at that time.

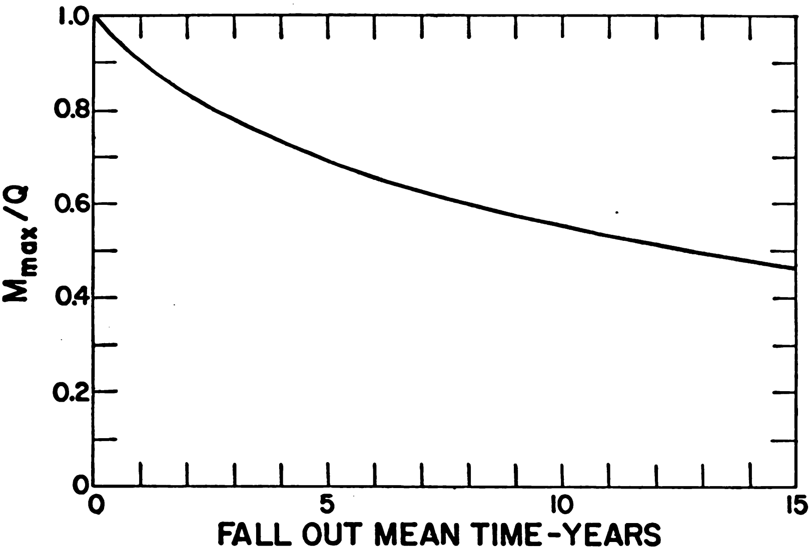

FIGURE 3. Dependence of maximum level of deposition on mean time of fallout.

TABLE II.—*Present and predicted maximum levels of Sr^{90} surface deposition* [1]

Area	Level October 1956 (mc/mi^2)	Maximum level 1975 (mc/mi^2)
Midwestern United States	22	29
Between 60° N. and 10° N. latitude	16	23
Rest of world	3.6	10
World average	[2] 8	[2] 15

[1] Assuming products of 24 MT fission in the stratosphere Jan. 1, 1957, and a fallout mean time of 10 years.
[2] Calculated by weighting for respective areas, taking 35 percent of earth's surface as lying between 60° N. and 10° N. latitude.

As stated previously, these figures assume uniform world-wide distribution of the material now in the stratospheric reservoir and no more weapon tests. Under these conditions, the area in the midwestern United States would be expected to reach a level of about 29 mc/mi^2. The area between 60°N and 10°N latitude may reach about 23 mc/mi^2, and the rest of the world may reach a

level of about 10 mc/mi². These values are general levels only, assuming uniform distribution within the respective areas. Local meteorological conditions will produce nonuniformities within these general regions. Recent data (10) suggest that some areas of the United States (South Dakota, Iowa, Michigan, New York) already may have deposition levels of about 29 mc/mi² (January 1957).

4. INCORPORATION OF SR^{90} INTO THE BIOSPHERE

When Sr^{90} falls upon the earth's surface, it is taken into plants through the root system in relation to the available calcium in the soil. That which settles directly on vegetation may remain as surface contamination, or a part of it may enter the plant through foliate absorption. When plants are eaten by animals, Sr^{90} deposited directly on the surface or incorporated in the plant (by foliate absorption or from the soil) is absorbed by the animal along with calcium. When plant and animal products (e. g., milk) are eaten by man, the Sr^{90} they contain becomes incorporated with his body calcium and deposits predominantly in the bone.

It is reasonable to assume that strontium may be discriminated against with respect to calcium in passing along the ecological chain. For example, the Sr^{90}/Ca ratio in the bones of people may be expected to be lower than the Sr^{90}/Ca ratio in the soil, which is the beginning of man's food chain.

Information regarding Sr^{90} in relation to man and his environment may be obtained from data on stable strontium. Turekian and Kulp have reported stable strontium to calcium ratios in human bone (11) and in sedimentary and igneous rocks (12). If it is assumed that the average stable strontium to available calcium ratio in the world's soils is essentially equal to that of the rocks from which they are formed, the over-all discrimination ratio (OR) against strontium over calcium in passing along the ecological chain from soils to bone is about 0.1, $\left[\text{i.e., } \frac{(Sr^s/Ca)_{bone}}{(Sr^s/Ca)_{soil}} = \sim 0.1\right]$.

Data on stable strontium content of human bone ash were reported by Hodges *et al* (13) and show conclusively that, under equilibrium conditions, stable strontium is equally distributed throughout the skeleton (Table III). Their results were confirmed by others (11, 14), and leave no doubt but that man's bones will eventually come into equilibrium with the Sr^{90} contamination in his environment.

TABLE III.—*Stable strontium content of human bones*

Sample	Sr in bone ash (percent)			
	Parietal	Vertebra	Rib	Femur
Fetal [1]	0.016	0.016	0.017	0.017
All ages [2]	0.023	0.022	0.022	0.022
1914 cadavers	0.027	------------	0.027	0.025

[1] Fetal bones showed range of 0.015 to 0.019 percent.
[2] All-age group showed no significant increase with age when analyses were compared in 5 age groups.

Alexander, Nasbaum and MacDonald (15) obtained excellent data on the discrimination against strontium over calcium in going from plants to milk. They compared the stable strontium to calcium ratio of cows' milk with that of the feed the cows consumed and found that $\frac{(Sr^s/Ca)\text{ milk}}{(Sr^s/Ca)\text{ feed}} = 0.13$. These authors (16) also studied the relative uptake of stable strontium and calcium from the diet by a variety of rodents, including rabbits and kangaroo rats from the Nevada desert. They found an average $\frac{(Sr^s/Ca)\text{ bone}}{(Sr^s/Ca)\text{ food}} = 0.24$. They suggested that this retention ratio might be used to predict the skeletal uptake of Sr^{90} by humans, through continued consumption of contaminated food.

Attempts are being made also to determine the over-all Sr^{90} discrimination ratio in going from soils to human bone by radioactive tracer studies of the discrimination factors (DF) that occur at the various steps along the ecological chain.

The discrimination factor most difficult to establish is the one from soils to plants (DF_1). It is dependent, among other things, on type of soil, available soil calcium, type of plant and perhaps on rainfall, all of which may vary greatly with geographic location. Menzel (17) obtained a soil-to-plant discrimination factor $\frac{(Sr^{90}/Ca)\,plant}{(Sr^{90}/Ca)\,soil}=0.7$, for four widely different soil types using both radioactive and stable strontium. Larson (18) and Bowen and Dymond (19) have obtained comparable values.

Comar (20) has determined the discrimination factor from plants to milk (DF_2) using Sr^{85} and Ca^{45} and found that $\frac{(Sr/Ca)\,milk}{(Sr/Ca)\,plants}=0.14$, which is in good agreement with the value of 0.13 obtained from stable strontium data (16). Comar also studied the discrimination factor (DF_3) in going from milk to human bone following single and multiple feeding and found the radio $\frac{(Sr/Ca)\,bone}{(Sr/Ca)\,milk}=0.5$.

Experiments by Laszlo (21) on the discrimination factor (DF_4) from plants directly to human bone gave a value for $\frac{(Sr/Ca)\,bone}{(Sr/Ca)\,plant}=0.25$, which agrees with radioisotope studies in rats conducted by Comar (22) and with stable strontium data on rodents (16).

The over-all ratio ($OR_{bone-soil}$) in going from soil to human bone via the diet may be estimated from the various discrimination factors and the fraction of dietary calcium derived from diary products and directly from other sources. The Department of Agriculture, on the basis of United States retail sales, has estimated that 65 percent of the dietary calcium for all ages comes from dairy products and 35 percent from other sources. On this basis, $OR=(0.65\times DF_1\times DF_2\times DF_3)+(0.35\times DF_1\times DF_4)=(0.65\times 0.7\times 0.13\times 0.5)+(0.35\times 0.7\times 0.25=0.09$. The above value is in agreement with the crude estimate made from stable strontium considerations, and represents a reasonable general average of the values derived at a recent Washington Conference on "Deposition and Retention of Ingested Sr^{90} in the Skeleton" (23). This Committee reported also that the ($OR_{bone-diet}$) for a six-month-old child might vary from 0.041 to 0.13, which would give an average value for ($OR_{bone-soil}$) of 0.06. The above information on the over-all discrimination factor against strontium during passage up the ecological chain from soils to human bone via the diet is summarized in Figure. 4 and may be used to estimate the average present and future maximum Sr^{90} levels in bone as a result of weapons tests to date. In so doing, however, it must be re-emphasized that these values are for *ecological* discrimination and apply only to discrimination against Sr^{90} in progressing up the life cycle. An ecological discrimination factor automatically assumes that the calcium and strontium are uniformly mixed in soil and are equally available to the depth of the plant feeding zone. No allowance is made for direct foliar absorption of Sr^{90}, for its dilution with a greater reservoir of available soil calcium through plowing, or for the possibility that it may become less available with time through soil binding and leaching. Much of the disagreement between the over-all discrimination factors reported by Libby (10) and those given above is more apparent than real, because of failure to make clear distinction between over-all discrimination and over-all *ecological* discrimination.

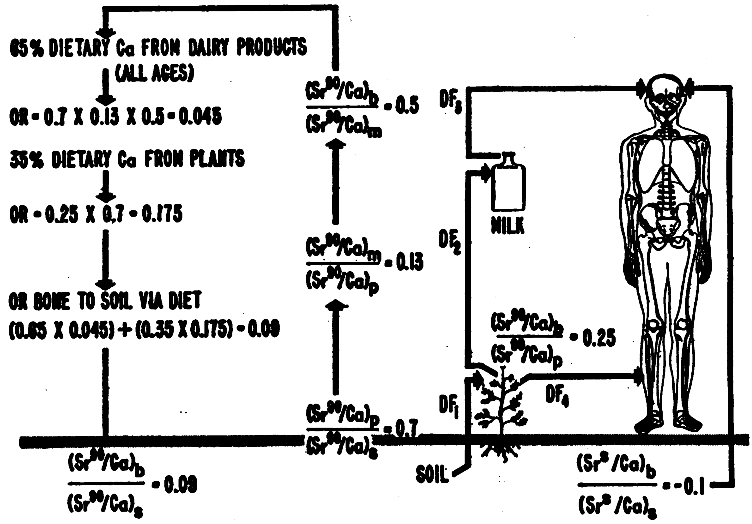

FIGURE 4. Discrimination against strontium with respect to calcium in passing up the food cycle from soil to man.

5. PREDICTED PRESENT AND FUTURE Sr^{90} AVERAGE MAXIMUM LEVELS IN BONE

Sr^{90} content of the bones of young children at the time of maximum biospheric contamination is assumed to be of major concern because children are believed to be more sensitive to radiation and their entire skeletons will be formed under steady state conditions with the Sr^{90} contamination of the environment.

From the present and predicted maximum Sr^{90} surface deposition levels (Table II) and the Sr^{90} soil-to-bone discrimination ratios derived in the previous section, present and future average maximum Sr^{90} levels in bone can be predicted.

Assuming an average of 20 g available Ca/ft² of soil to a depth of 2½ in. (2), 1 mc of Sr^{90}/mi² is equivalent to 1.8 $\mu\mu$c/g available calcium. Multiplication of the Sr^{90} surface deposition levels in Table II by 1.8 gives the specific activity of the available soil calcium. The specific activity of the soil calcium times the Sr^{90} discrimination ratio of 0.06 (for six-month-old child) should give the average maximum specific activity (in $\mu\mu$c/g) of the bone calcium of young children under steady state conditions. Multiplication of the specific activity of the available soil calcium by the Sr^{90} discrimination ratio of 0.09 should give the average maximum specific activity of calcium laid down in the adult skeleton through exchange and bone remodeling during the period of environmental contamination. Present and future average maximum Sr^{90} levels in the skeletal calcium of young children at equilibrium and in newly formed adult bone calculated in the above manner are given in Table IV. As the diet of children changes, they may be expected to approach a Sr^{90} equilibrium level comparable to the level predicted for newly formed adult bone.

TABLE IV.—*Predicted present and future average maximum Sr^{90} levels in bone*

Area	Predicted maximum, fall 1956		Predicted maximum, 1975	
	Children at equilibrium [1] ($\mu\mu$c/g Ca)	New adult bone [2] ($\mu\mu$c/g Ca)	Children at equilibrium [1] ($\mu\mu$c/g Ca)	New adult bone [2] ($\mu\mu$c/g Ca)
Midwest United States	2.4	3.6	3.1	4.7
60° N. to 10° N. latitude	1.7	2.6	2.5	3.7
Rest of world	0.4	0.6	1.1	1.6
World average	0.9	1.3	1.6	2.4

[1] Assuming steady state conditions, 20 g available soil Ca/ft² of soil to depth of 2½ in. and ($OR_{bone-soil}$) = 0.06.

[2] Specific activity of calcium of new bone formed by exchange plus skeletal remodeling, assuming $OR_{bone-soil}$) = 0.09.

These data suggest a present average maximum equilibrium level of 1.7 $\mu\mu c$/g Ca in bones of young children and 2.6 $\mu\mu c$/g Ca in newly formed adult bone in the world population belt between 60°N and 10°N latitude. Calculation of average maximum equilibrium levels in about 1975 from the predicted soil levels gives 2.5 and 3.7 $\mu\mu c$/g Ca for young children and adult bone, respectively, assuming no more detonations after Operation Redwing in the summer of 1956.

The data in Table IV are subject to the uncertainties in predicted present maximum levels of surface deposition and to the uncertainties involved in the derivations of the bone-to-soil discrimination ratios. The greatest uncertainty in the values is probably due to their dependence on available soil calcium with which the Sr^{90} is mixed.[8] Available soil calcium may vary within the United States from about 1 to 100 g/ft^2 to a depth of 2½ in. The relative Sr^{90} uptake would be higher in areas with abnormally low available soil calcium. The available calcium with which the Sr^{90} is actually mixed is dependent also on the average depth of the feeding zone of all the various types of plants responsible for the introduction of calcium into man's food chain.

Derivations of the discrimination ratios assume also that average infant and "all-age" diets of the world population are comparable to those of the United States and assume Sr^{90} is in equilibrium in the soil and make no allowance for the fraction entering the food chain through direct fallout on vegetation.

Kulp *et al.* (24) recently reported Sr^{90} analyses of 484 bone samples from persons of all ages collected at 17 stations in a worldwide sampling network. Most of these samples came from the area between 60°N and 10°N latitude, and the majority were collected during 1955 and the spring of 1956. The average Sr^{90} value for all ages was 0.12 $\mu\mu c$/g Ca. A few results were ten times the average and a definite age effect was observed. The bones of young children showed Sr^{90} values three to four times the average, which was attributed to the greater portion of active bone in children. The average Sr^{90} content of 64 bone samples in the 0- to 4-year-age group was reported as 0.31 $\mu\mu c$/g Ca, after dividing results from rib samples by 2 and those from vertebra by 4 to obtain an average for the total skeleton. This adjustment to obtain a skeletal average was predicated on Sr^{85} distribution studies in adult cancer patients given a single injection. The data in Table III suggest that adjustment of rib and vertebra results to obtain a skeletal average may not be entirely valid for children, in which a major portion of the skeletal calcium was laid down during the period of Sr^{90} environmental contamination. The adjustment, however, in the case of adult bone samples (in which the majority of the Sr^{90} was laid down during a contamination period relatively short compared to the age of the individual) might be justified. These adjusted values, in the case of adult bone, might be a measure of new bone formation by exchange plus skeletal remodeling during the period of contamination. On the basis of these data, it should be possible to postulate an internally consistent model for Sr^{90} deposition in the skeleton of persons of all ages, taking into consideration the rate of increase of environmental contamination and the rate of calcium deposition by skeletal growth and bone remodeling plus exchange as a function of age. Figure 5, derived from data given by Mitchell (25), shows the total deposition of skeletal calcium in males as a function of age and their rate of skeletal accretion in per cent of calcium deposited per year. This figure also shows the rate of increase in integrated Sr^{90} fallout in the Chicago milk-shed area from 1953 through 1957 and suggests a doubling time of about one year (3).

Using the rate of skeletal accretion (Table V, Fig. 5), increase in integrated fallout and Kulp's average Sr^{90} bone values for the various age groups, it should be possible to calculate the maximum average equilibrium level of Sr^{90} as of the fall of 1955. The specific activity of the calcium in the bones of children should depend on the fraction of the skeletal calcium laid down by all mechanisms during the period of environmental contamination, and the specific activity of the bone calcium of adults should depend on the per cent of skeletal calcium equilibrated during the same period by new bone formation through bone remodeling plus exchange.

[8] The assumption of 2½ in. as the effective depth for Sr^{90} is subject to great uncertainty. Plowing will result in mixing to a depth of about 6 in., and no allowance is made for the possibility that some of the Sr^{90} may become unavailable to plants (as is some of the soil calcium) and over long periods of time some may be removed from the soil by leaching.

TABLE V.—*Yearly accretion of skeletal calcium in males*

Age (years)	Calcium in total skeleton [1] (g)	Increase per year (g)	Fraction of equilibrium Sr^{90}/Ca	Age (years)	Calcium in total skeleton [1] (g)	Increase per year (g)	Fraction of equilibrium Sr^{90}/Ca

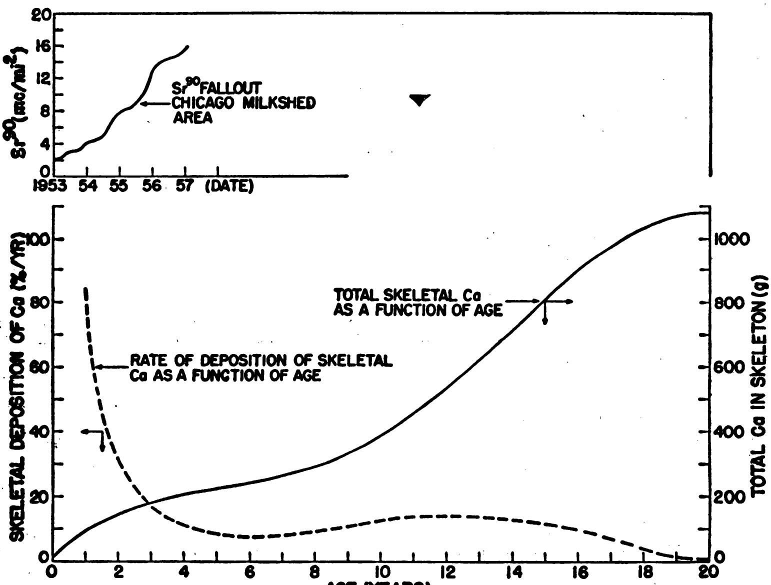

FIGURE 5. Rate of accretion of skeletal calcium in relation to rate of environmental contamination.

It is assumed that each yearly increment of skeletal growth will contain Sr^{90} at a concentration corresponding to the Sr^{90} build-up in the biosphere for that year. For a first approximation, the skeleton will be regarded as a unit and the Sr^{90} burden averaged over the entire skeleton. As better data are available, it will be profiable to consider the individual bones separately, both in terms of their Sr^{90} burden and their radiosensitivity.

Calculated values for the apparent fraction of equilibrium Sr^{90}/Ca ratio as a function of age, based on skeletal growth rate alone and a yearly doubling time of the Sr^{90} level, are given in the last column of Table V and are shown by the solid curve of Fig. 6. The method of calculation is best explained by an example. For an eight-year-old skeleton (Table V) in 1956 the last 33 g of calcium contain an equilibrium concentration C of strontium, and thus a total amount of strontium equal to 33 times C. The previous year's deposition of 26 g would have been formed with a concentration C/2 of strontium and would con-

tribute 13 C. The fifth and fourth years' growth would incorporate 20 C/4 and 18 C/8 units of strontium, respectively. The total strontium in the skeleton at age eight is, therefore, (33+13+5+2.5) C, or 53 C. (A four-year cut-off is used since large-scale testing began in 1952. Actually, the series is converging so rapidly that the cut-off has little effect.) If the entire skeleton had been in equilibrium with the Sr^{90} level of the environment in the eighth year, it would have contained 297 C units of Sr^{90}. The fraction of equilibrium is, therefore, 53 C/297 C, or 0.18.

The points in Fig. 6 represent Kulp's unadjusted values for subjects under 20 years of age and his adjusted data for adults normalized to the 0- to 4-year age group as representing 59 per cent of equilibrium Sr^{90} concentration.

At age 24 (4 years beyond the age at which skeletal growth stops) these data show that about 10 per cent of the skeletal calcium was involved in bone remodeling plus exchange during the period of environmental contamination. The data further suggest that the amount of calcium involved decreases with age, which is in keeping qualitatively with classic concepts of bone physiology. If a similar fraction of the skeletal calcium of growing subjects is involved in exchange plus remodeling, then the Sr^{90} levels in children would be proportionally higher than the curve based on skeletal calcium accretion alone. This indeed appears to be the case and indicates that the major factors have been considered in constructing the model.

If the fraction of remodeling and exchange for children's bones is similar to that observed for adults, then the accretion curve below age 20 should be raised proportionately, to give the over-all apparent fraction of equilibrium Sr^{90}/Ca ratio as a function of age (dashed line, Fig. 6). This curve permits the use of adequate bone data from any age group to predict the average maximum equilibrium Sr^{90} bone level and indicates an average maximum equilibrium level of 0.9 $\mu\mu c/g$ Ca at the end of 1955.

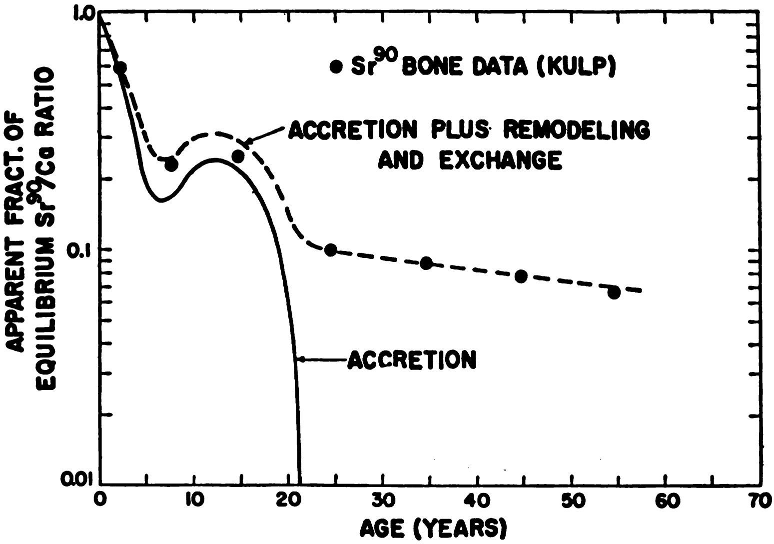

FIGURE 6. Apparent fraction of equilibrium Sr^{90}/Ca ratio as a function of age.

Sr^{90} content of skeletons of stillborns (3) during 1955 averaged about 0.5 $\mu\mu c/g$ Ca, which gives an average maximum equilibrium level of 1.0 when the placental discrimination factor of 0.5 (26) is considered. Bryant *et al* (27) in England reported analyses of 28 bone samples from subjects of all ages collected about January of 1956. Eight samples from persons ranging from 3 months to 3½ years old (average 1⅓ years) average 0.9 $\mu\mu c$ Sr^{90}/g Ca, and 11 subjects ranging from 20 to 65 years of age (average 36 years) averaged 0.07 $\mu\mu c$ Sr^{90}/g Ca. after dividing all rib results by 2. The predicted average maximum Sr^{90} equilibrium level about January 1956, based on these age groups, is 1.0 and 0.9 $\mu\mu c/g$, Ca, respectively.

Since the Sr^{90} environmental contamination level continued to rise during 1956, the predicted average maximum Sr^{90} equilibrium level of new bone as of the first of 1957 is about 1.8 $\mu\mu c/g$ Ca, which agrees quite favorably with the value of 1.7 for October 1956 derived from ecological discrimination factors (Table IV). Extrapolation to 1975, assuming no more weapons tests, gives a maximum average equilibrium level in young children of 2.6 $\mu\mu c/g$ Ca. If it is assumed that 1.8 $\mu\mu c$ Sr^{90}/g Ca represents present equilibrium conditions for the area between 60° N and 10° N latitude, values for the upper midwestern and eastern United States and the rest of the world can be calculated from the present and predicted average maximum levels of Sr^{90} surface deposition given in Table II. Results calculated in this way are compared in Table VI with young children's equilibrium values (Table IV) derived from ecological discrimination factors.

TABLE VI.—*Comparison of average maximum Sr^{90} equilibrium levels in skeletons of young children, derived from bone equilibrium and ecological discrimination considerations*

Area	Predicted maximum 1957		Predicted maximum 1975	
	Bone data ($\mu\mu c/g$ Ca)	Ecological data ($\mu\mu c/g$ Ca)	Bone data ($\mu\mu c/g$ Ca)	Ecological data ($\mu\mu c/g$ Ca)
Upper Midwestern and Eastern United States	2.5	2.4	3.2	3.1
60° N. to 10° N. Latitude	1.8	1.7	2.6	2.5
Rest of world	0.4	0.4	1.1	1.1
World average	0.9	0.9	1.7	1.6

These data show good agreement between the two methods of estimation.

Other observers have estimated average maximum Sr^{90} equilibrium levels in bone usually by methods that involved surface deposition levels and various ecological discrimination factors.

Libby first estimated the maximum equilibrium level in the United States and Europe in about 1970 at about 11 $\mu\mu c/g$ Ca (2). This estimate was based on the assumption that bone calcium would reach a Sr^{90} level approximately 70 per cent of that of available soil calcium. He later estimated a maximum average in the 1970's of 4 to 10 $\mu\mu c/g$ Ca (3) on the basis that calcium of bone would come into equilibrium at 10 per cent of the Sr^{90} content of available soil calcium. More recently he has estimated the average maximum bone equilibrium level in the spring of 1957 at 1.7 to 3.9 $\mu\mu c$ Sr^{90}/g Ca. The latter estimate was based on an over-all discrimination ratio of 1/13 to 1/30 for surface deposition levels of 25 mc Sr^{90}/mi^2 between 10°N and 60°N latitude. Because of the rate of decay of Sr^{90}, he concluded that the equilibrium bone concentration would be very little higher in the 1970's when the maximum soil contamination level is reached.

Kulp (24) estimated the world-wide average maximum equilibrium Sr^{90} bone level at 0.6 $\mu\mu c/g$ Ca in the fall of 1955 and at 1.3 $\mu\mu c/g$ Ca in about 1970, assuming no more weapons tests after the 1956 series. His estimates for the United States bone value were 0.9 $\mu\mu c/g$ Ca for the fall of 1955 and about 2$\mu\mu c/g$ Ca by 1970. All estimates were based on Sr^{90} surface deposition levels and ecological discrimination factors.

Eisenbud (4) made an estimate of the maximum average bone level on the assumption that bone calcium would come into equilibrium with the Sr^{90} in calcium from milk. In the summer of 1955, New York milk contained 2.5 $\mu\mu c$ Sr^{90}/g Ca, corresponding to a surface deposition level in the area of 6.5 mc/mi^2. Since he expected a maximum surface deposition in this area of about 21.5 mc/mi^2 in about 1970 when the stratospheric inventory of Sr^{90} is deposited, he estimated an average maximum bone level of 8.3 $\mu\mu c/g$ Ca. Admittedly, his estimate was pessimistic in that it ignored the possibility of transient high Sr^{90} values in milk resulting from cows eating fresh fallout on the surface of plants and assumed no discrimination between strontium and calcium in going from milk to bone. Introduction of the milk-to-bone discrimination factor of 0.5 lowers his estimate to 4.1 $\mu\mu c/g$ Ca.

Sr^{90} data on milk samples might be used to give a general estimate of the average maximum equilibrium level in bone. Chicago (2), United Kingdom

(27), New York (4), and Turkish milk (2) samples during the fall of 1955 and spring of 1956 averaged about 2.5$\mu\mu c$ Sr^{90}/g Ca. Ignoring all factors other than the discrimination factor (DF_3) of 0.5 in going from milk to bone and the one-year doubling rate for environmental contamination, the average maximum Sr^{90} equilibrium bone level in the fall of 1956 would be 2.5 $\mu\mu c$/g Ca. Extrapolated to 1975, the value would be 3.5 $\mu\mu c$/g Ca.

The various estimates of average maximum Sr^{90} equilibrium levels show a trend toward general agreement with those based on the most recent available bone data and the latest opinions regarding ecological discrimination factors (Table VI).

The most troublesome feature of the above considerations is that all values are average maximum equilibrium levels of Sr^{90} and make no allowance for local concentrations of fallout due to meteorological factors, variations in available soil calcium, dietary patterns and habits, nutritional state of segments of the population, etc. Frequency distribution patterns have been reported for stable strontium (11), natural radium (28) and Cs^{137} (7) in man. All these nuclides show essentially normal distributions with standard deviations of about 35 per cent, which suggests that the range ($\pm$ 3σ) of Sr^{90} equilibrium bone levels as of the first of 1957 (based on an average of 1.8 $\mu\mu c$/g Ca) should lie between about 0.3 and 4 $\mu\mu c$/g Ca.

On the basis of the above distribution patterns, Libby (10) has stated (at steady state among people *living in a given locality*) only one person in about 700 will have more than twice the average Sr^{90} burden, and the chances of anyone having as much as three times the average will be about one in 20 million. Presently the Sr^{90} measurements of bone samples from subjects of all ages show a much greater scatter than indicated by a standard deviation of 35 percent. The greater scatter of the observed values is due largely to the fact that samples came from many localities and (because of the relatively short period of environmental contamination and the age dependence of Sr^{90} deposition) represent varying degrees of equilibrium conditions. As stated by Libby, the spread may be expected to decrease as equilibrium is approached, and a study of the distribution of all bone data when normalized to equilibrium according to the upper curve of Fig. 6 is underway.

Local meteorological conditions will result in increased intensity of fallout in certain localities. The worst possible situation that could come about would be for these "hot spots" to coincide with localities of low available soil calcium in which the population grew up and lived in provincial isolation. Libby (10) has considered this problem in view of the averaging which occurs in food distribution systems and has postulated that a factor of 5 encompasses the total variation due to all factors, including soil calcium deficiencies.

6. SIGNIFICANCE OF SR^{90} LEVELS IN THE POPULATION

A. *Basis of Maximum Permissible Levels of Radiation*

Consideration of the basis of maximum permissible levels of radiation is essential to the evaluation of the potential hazard of Sr^{90} contamination to the general population. Human experience through diagnostic and therapeutic use of X and gamma rays and extensive animal experimentation with all types of radiation have demonstrated conclusively the production of deleterious biological effects. These effects are manifest as early physiologic aging resulting in life shortening, mutations, irregularities in hematopoietic function (some of which result in increased incidence of leukemia), and specific organ or tissue changes such as cataracts of the lens of the eye and tumors of bone.

Damage from ionizing radiations may occur from radioactive isotopes deposited in the tissues and organs, as well as from radiations originating from an external source.

Occupational Exposure.—Maximum permissible levels for most radioisotopes as applied to occupational exposure are calculated on the premise that no critical organ or tissue will receive an average dose rate greater than 300 mrem per week (the maximum permissible dose rate for external whole body radiation), assuming uniform distribution of the isotope throughout the tissue or organ. It is recognized that calculations based on average dose or uniform distribution in a critical organ or tissue may lead to considerable error, since some radioisotopes are unevenly deposited. Although the average dose rate to a critical organ may be 300 mrem per week, some portions of the organ may receive considerably less than the average and others correspondingly more. This error, however, is be-

lieved to be offset at least in part by the fact that 300 mrem is considered the acceptable weekly exposure to the entire body or the blood-forming organs, and therefore may be overly conservative when applied to a small element of tissue.

The maximum permissible levels of radionuclides that localize in bone (i. e., Sr–90) are determined by direct comparison with the 0.1 μc maximum permissible burden for radium. Limited human experience has indicated conclusively that small amounts of radium fixed in the skeleton will produce osteoporosis, necrosis, and sarcoma (29). Bone changes in radium dial painters and persons who received radium therapeutically provide the basis for the value of 0.1 μc. The maximum permissible levels of other bone-seeking radioisotopes are established on the premise that the amount fixed in the bone will not result in greater probability of biological effect than that produced by 0.1 μc of fixed radium.

Derivations of formulae for the calculation of maximum permissible levels, their parameters and pertinent information on individual nuclides are given in the Handbooks of the International (8) and the National (30) Commissions on Radiological Protection. These handbooks provide the only official sources of maximum permissible levels for the various radionuclides from the standpoint of internal absorbed dose. All values presently published in the handbooks refer to continuous occupational exposure.

Nonoccupational Exposure.—Maximum permissible levels for nonoccupational exposure or exposure of a large segment of the general population were established by taking arbitrarily one-tenth of the value for working personnel (8, 30, 31).

The rationale behind a lower value for the general population is based on the numbers involved in the two groups at risk and the increased heterogeneity of the general population over that of the select working group. The latter group is composed of supposedly healthy workers (over 20 years of age), while the general population group may contain children, pregnant women, the undernourished, the sick and the old. On the assumption that frequency of response to radiation stress follows a Gaussian distribution (Fig. 7), the probability of injury of a few individuals from a specified dose increases with increase in size and heterogeneity of the group at risk.

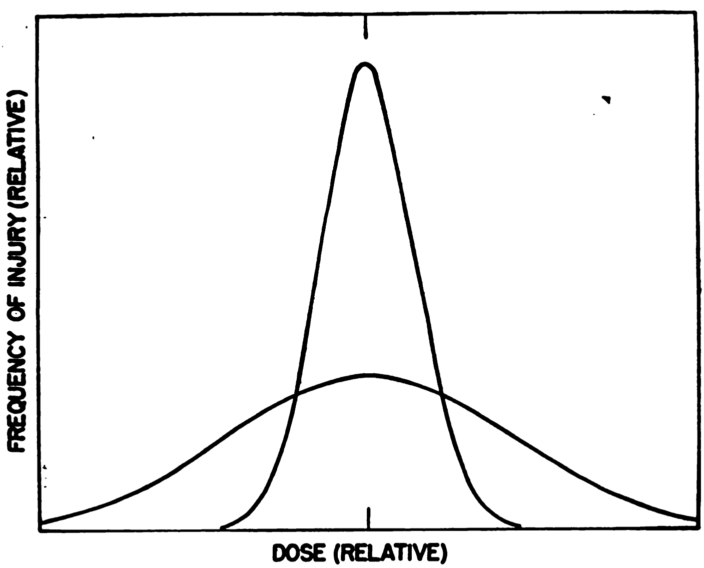

FIG. 7.—Effect of increased heterogeneity of the population on Gaussian distribution of frequency of injury as a function of dose.

The maximum permissible level of Sr^{90} for workers is set at 1 μc in the total adult skeleton, and the recommended level for the general population is set at 0.1 μc[4] (9, 32, 33). The permissible levels of radiation exposure (including that from Sr^{90}) is predicated on the assumption that chronic and/or delayed effects of radiation are threshold phenomena (Fig. 8). That is to say, there is a threshold dose below which effect rapidly becomes insignificant and above which effect increases expenentially over a limited dose range. If this is indeed the case, 100 $\mu\mu c$ Sr^{90}/g Ca must be looked upon as a true maximum permissible level and not an average value for the general population.

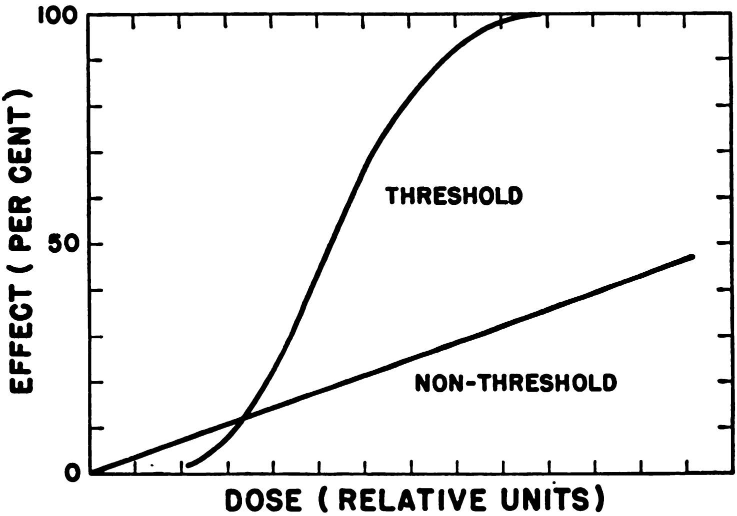

Figure 8.—Threshold versus nonthreshold effect in relation to increasing radiation dose.

Threshold versus Nonthreshold Response.—At the present time it is impossible to say whether leukemogenic and sarcogenic responses to chronic radiation dosage are threshold or nonthreshold relationships. Argument for a linear relationship between incidence of leukemia and radiation dose was presented recently by Lewis (34). His argument was based on all major sources of human data and included a consideration of the Japanese atomic bomb survivors, the British cases of X-ray treated spondylitis patients, X-ray treated cases of thymic enlargement, practicing radiologists and spontaneous incidence of leukemia in Brooklyn, New York. Radiation as a carcinogenic agent has been discussed at length by Brues (35), who stated that the relation between radiation dose and carcinogenic effect is not easy to find and a critical experiment has yet to be done which will clearly indicate, even in a single instance, what the relation is over more than a small range of dosages. While admitting that it is not known, he proposes that a threshold relationship between radiation dose and tumor incidence does exist (36).

Genetic response to external radiation indeed appears to be linear and a given increment of dose produces a corresponding equal increment of effect, regardless of position on the dosage scale (Fig. 8). If it is assumed that all chronic effects of radiation are linear, it would seem more reasonable to establish permissible levels for the general population on the basis of probability of risk averaged over the entire group. Present incidence of bone sarcoma and of leukemia averaged over the entire population is about 2 and 6 per 100,000, respectively. About 10 percent of the natural incidence of leukemia (34) (and perhaps of bone sarcoma) may be attributable to natural radiation background. If this is true, doubling the natural background dose to the bone might be expected to increase the inci-

[4] There is about 1 kg of calcium in the adult human skeleton; therefore, the MPL of Sr^{90} in the general population is equivalent to 0.1 μc Sr^{90}/kg Ca = 100 mμc/kg Ca = 100 $\mu\mu c$/g Ca = 100 Sunshine Units (2).

dences of bone tumors and leukemia to 2.2 and 6.6 per 100,000, respectively. Such a small increase distributed through the general population may be undetectable, and 100$\mu\mu$c Sr^{90}/g Ca (which would about double the background skeletal dose) may be regarded by some as an acceptable average maximum equilibrium for the general population.

B. Hazard from Present and Predicted Sr^{90} Levels

The significance of the general hazard of present and predicted levels of Sr^{90} in bone can be evaluated only in relation to human experience, which is indeed inadequate. Bone sarcoma has resulted from a fixed skeletal burden of 3.6 μc of pure Ra^{226}, and nondeleterious bone changes have been observed in persons having only 0.4 μc for a period of 25 years (37). Necrosis and tumors of the bone have occurred also several years after large doses of X-ray (38), and consideration of human experience with leukemogenic effects of X and gamma radiation (9, 34, 39) suggests that about 80 rads may double the incidence of leukemia.

The only other human experience with which present and predicted levels of Sr^{90} may be compared is that arising from natural background radiation. Natural background dose to the bone (during a 70-year lifetime) may vary from about 8 to 38 rem (40). The major contribution to background variation is differences in the radium levels of soils and minerals. The average natural skeletal radiation dose rate was carefully evaluated by Dudley and Evans (41) and their data are shown in Table VII.

TABLE VII.—*Average natural background radiation dose rate to the skeleton (Dudley, Evans)*

Source of radiation	Skeletal dose rate (mrem/year)	Total dose to age 70 (rem)
K^{40} (internal)	8	0.56
Ra^{226} (internal)	12	0.84
MsTh (internal)	12	0.84
RaD (internal)	12	0.84
Cosmic rays (external)	30	2.1
Local gamma rays (external)	60	4.2
Total	134	9.4

Table VIII (after Brues (42)) gives a general summary of estimated skeletal radiation doses from accepted maximum permissible levels and from present and predicted Sr^{90} burdens in relation to human experience. The maximum permissible level of Sr^{90} (100 $\mu\mu$c/g Ca) is estimated to deliver about 8 rads [5] to the skeleton during a 70-year life-time. This is comparable to the average natural background dose to the bone for the same time period and a factor of ~4 below the maximum natural background dose to which small segments of the general population may be exposed as a result of differences in altitude and natural radium content of soils and minerals. It is a factor of 40 below the lowest skeletal dose which has produced minimal nondeleterious bone changes. These data suggest that the present average maximum Sr^{90} equilibrium level in children will result in a life-time radiation dose of approximately 2 per cent of the accepted maximum permissible level for the general population. The predicted average maximum level of Sr^{90} (from bone data) in about 1975, assuming no further weapons tests, corresponds to a skeletal radiation dose of about 2.6 per cent of the maximum permissible level with a spread ($\pm 3\sigma$) of about 0.5 to 6 per cent.

The biological significance of present and predicted Sr^{90} average maximum equilibrium levels and maximum permissible levels for occupational and non-occupational exposure is summarized in Table IX.

[5] Eight rads is the calculated dose assuming incorporation to age 20 and decay to age 70 with no more incorporation. If equilibrium were maintained, the calculated skeletal dose would be about 21 rads. Since some but not all of the skeleton undergoes remodeling plus exchange, somewhere between 8 and 21 rads is probably more correct.

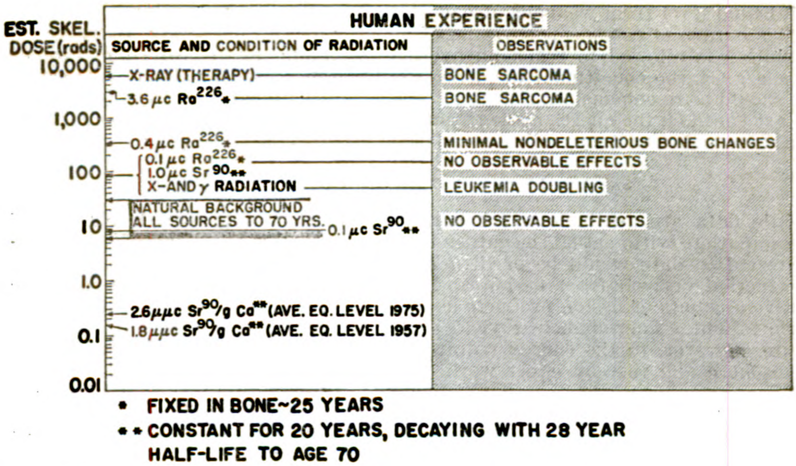

TABLE IX.—*Biological significance of present and predicted Sr^{90} average maximum equilibrium levels and maximum permissible levels for occupational and nonoccupational exposure*

Sr^{90} level	MPL nonoccupational exposure (100 $\mu\mu$ c/g)	MPL occupational exposure (1,000 $\mu\mu$ c/g)	Minimum bone changes	Minimum sarcoma dose	Leukemia doubling dose
Present (1.8 $\mu\mu$ c/g Ca)[1]	1/50	1/500	1/2,000	1/20,000	1/500
Predicted (2.6 $\mu\mu$ c/g Ca)[1]	1/40	1/400	1/1,400	1/14,000	1/360
100 $\mu\mu$ c/g (MPL nonoccupational exposure)	----------	1/10	1/40	1/400	1/10
1,000 $\mu\mu$ c/g (MPL occupational exposure)	10	----------	1/4	1/40	1

[1] Average maximum equilibrium level of Sr^{90}, probability slight that many will run more than 3 times average.

The most interesting comparison made in Table IX is that between Sr^{90} levels and the leukemia doubling dose, assuming a nonthreshold relation between incidence and radiation exposure. These data indicate that the predicted average maximum equilibrium level of Sr^{90}, assuming no more weapons tests after Operation Redwing (Fall 1956), is 1/360 of the leukemia doubling dose. Theoretically, this level is equivalent to an increase in leukemia incidence of 1.7 cases per 10 million population. The rate in some localized areas may be several times higher, but averaged over the world population of 2.6 billion, this would produce an increased lukemia burden of about 400 cases per year. If the entire world population is allowed to reach an average maximum Sr^{90} equilibrium level of 100 $\mu\mu$c/g Ca, the average increase in world's leukemia burden would be about 16,000 cases per year, or about 5 to 10 per cent (34).

The above discussion entails the assumption that Sr^{90} beta radiation induces leukemia of the bone marrow origin at the same rate (per unit of absorbed dose) as X and gamma rays. Much of the beta radiation from Sr^{90} will be absorbed in the bone and not reach the hematopoietic tissues at all. Experiments by Brues *et al* (43) suggest that Sr^{89} (half-life 55 days, $E\beta=1.5$ Mev.) administered to mice is relatively more spectacular as an osteosarcogenic agent than a leukemogenic agent. Furthermore, leukemia was not a significant finding in the radium dial painters (29, 44) or in the radium-injection cases (37).

Human data on radiation-induced osteogenic sarcoma are not adequate to provide a basis for a sarcoma doubling dose or for an estimation of the per cent of normal incidence attributable to natural background. If, however, the same assumptions used for leukemia are applied to osteogenic sarcoma (nonthreshold response, 10 per cent of normal incidence of 2 per 100,000 attributable to natural background and a doubling dose of 80 rads), the predicted average maximum Sr^{90}

equilibrium level from weapons already tested would produce an increase in the world's burden of osteogenic sarcoma of about 150 cases per year. If the world population is allowed to reach an average maximum Sr^{90} equilibrium level of 100 $\mu\mu c$/g Ca, the bone tumor incidence would be increased by about 5,000 cases.

It should be re-emphasized that the above considerations are extremely tenuous and are based on the questionable assumption that the incidence of leukemia and bona sarcoma bear a linear relationship to radiation dose.

7. SR^{90} LEVELS IN RELATION TO WEAPONS TESTING

Little data are available which permit correlation of present levels of Sr^{90} contamination with actual megatons of weapons tested. Total of all weapons tested to date would be of little value without additional information on the fraction derived from fission and on conditions of firing which influence relative amounts of fission products deposited as local, tropospheric and stratospheric fallout. Thermonuclear yield *per se* does not produce Sr^{90}; it does contribute, however, to the energy required to carry the fission products into the stratosphere and thereby effect world-wide distribution. Libby (2, 3, 10) has provided estimates of the megaton equivalents of fission products that have been injected into the stratosphere and deposited over various regions of the earth. Based on these values, Kulp (24) estimated that present levels (Fall 1956) of environmental contamination (including the stratospheric reservoir) was the result of injection of products from about 50 MT of fission yield.

By simple proportionality he estimated biospheric injection of Sr^{90} from 35,000 MT of fission would bring the average maximum Sr^{90} equilibrium bone level of the world's population up to 100 $\mu\mu c$/g Ca (the MPL for occupational exposure). He used 1.3 $\mu\mu c$ Sr^{90}/g CA as the average maximum equilibrium level for the world population in 1970, assuming no more weapons tests. Kulp did not say that the average maximum level of the world population should be allowed to reach 1000 $\mu\mu c$ Sr^{90}/g Ca,[a] but apparently tried to show the relation between megatons of fission tested to date and a MPL familiar to all (45). Libby (2, 3) also has used the occupational MPL as a reference point in discussing the hazard to the world population. This practice has led to confusion of the public and criticism of the Atomic Energy Commission (46). The data in Table X (based on various estimates of 1970 equilibrium bone levels) show the estimated megaton equivalents fission yield that may be injected into the biosphere (all at once) to bring the Sr^{90} average maximum equilibrium bone values in the United States, the northern hemispheric fallout belt and the world up to the limits set for occupational and nonoccupational exposure. The table also shows the influence of various factors for nonuniformity of distribution and uptake on the estimates for the northern hemispheric fallout belt (in which the majority of the world's population is distributed) based on the average maximum level derived from bone data. *These data are presented primarily to emphasize the principal areas of uncertainty responsible for apparent disagreements among various authorities.*

---

[a] The Sr^{90} maximum permissible level accepted by the National and International Commissions on Radiological Protection as being applicable to large segments of the population is equivalent to 100 $\mu\mu c$/g Ca.

TABLE X.—*Sr^{90} levels in relation to megaton equivalents of fission products injected into the biosphere*

Source of equilibrium estimate and area	Estimated equilibrium 1970–75 ($\mu\mu c$ Sr^{90}/g Ca)	MT required to produce average MPL

Ave. × $\frac{1}{10}$ (for nonuniformity) [2]		2,000	200

[1] Eisenbud's value corrected for discrimination factor of 0.5.
[2] Indicated by spread in current bone data from all ages (24).

Inspection of the data in Table X shows a variation of about 300 in the megaton equivalents of fission products that may be injected into the biosphere, depending on whether one wishes to be ultraconservative and use the highest equilibrium bone value, the nonoccupational MPL and the largest safety factor for nonuniformity, or use the occupational MPL applied to the world average maximum bone level with no safety factor for nonuniformity. The most important point to these data is that they show that the major portion of the variaion is associated with two factors, (1) the maximum permissible level for Sr^{90} as applied to the fallout problem, and (2) the factor for nonuniformity of Sr^{90} distribution and uptake.

The most important question regarding the potential hazard of world-wide fallout to the general population is its relation to future weapons testing. If there is an upper limit to the amount of Sr^{90} that can be tolerated in the bones of the population, then the number of megaton equivalents of fission products that can be contributed per year to the biosphere by all nations must be limited.

Theoretically, the total yearly injection rate should be that amount which, at equilibrium, will not result in a significant fraction of the population exceeding the limit of safety. If a constant yearly injection rate of 1, 10 or 100 MT of fission is adhered to, in about 100 years the amount of Sr^{90} added to the environment will come into equilibrium with the rate of Sr^{90} decay, and continuation of weapons testing at that rate will result in no further increase in the average maximum equilibrium level in the bones of the population. At that time the average equilibrium bone level will be directly proportional to the yearly injection rate, i. e., if 10 or 100 megaton equivalents are injected per year, the average equilibrium bone level will be 10 and 100 times higher, respectively, than it will be if only 1 megaton equivalent is injected.

Only three unclassified reports concerning implications of future biospheric fission product injection rates have appeared. Campbell (5) mathematically related surface deposition to a constant stratospheric injection rate. His equation suggests Sr^{90} surface deposition levels may reach 30 times present values with continuation of the present rate of biospheric contamination for 100 years. His approach, however, makes no allowance for the tropospheric deposition rate. Libby (49) has developed an expression relating Sr^{90} surface deposition to a constant test rate, using a calculated ratio of rates of stratospheric to tropospheric injection of 4 to 7. Libby's calculation is based on a measured value of 30 mc Sr^{90}/mi^2 for the present cumulated fallout in the northeastern United States (one of the more highly contaminated spots in the world) and the assumption that the stratospheric reservoir presently contains the Sr^{90} from 24 MT of fision. Libby first estimated that the maximum equilibrium Sr^{90} deposition level should approach 8 times the present level (10). On re-

calculation of the ratio he obtained a value of 11 (49).[7] Using a build-up factor of 8 and assuming an ecological discrimination factor of 20 to 80 against Sr^{90} in going from soil to human bone, he estimated an average maximum bone equilibrium level of 5 to 20 $\mu\mu c$ Sr^{90}/g Ca for the population of the United States when equilibrium is reached. If the present rate is continued for 28 years, the average maximum level would reach only one-half of the above values (10). The general consensus of opinion (23) of the various specialists in the field of bone and mineral metabolism is that the discrimination factors used above are too high and that a factor of 10 to 20 is more realistic.

Stewart, Crooks and Fisher (48) estimated the concentration of Sr^{90} on the ground in the United Kingdom as 4.5 mc/km^2 on January 1, 1956, and the mean deposition rate as 2.3 mc/km^2/year. From these data the ground concentration in the U. K. as of January 1, 1957, would be about 17 mc/mi^2. They also estimated that an equilibrium value of about 500 mc/mi^2 (200 mc/km^2) of Sr^{90} may be reached in the U. K. in about 100 years if the present rate of biospheric contamination is continued. These data show a build-up factor of about 30 over present levels.

Predicted average maximum Sr^{90} bone levels, assuming continuation of the present biospheric contamination rate for about 100 years, are given in Table XI. These values were calculated from present (Fall 1956) bone equilibrium levels derived either from analyses or from ecological considerations assuming an ecological discrimination factor of 10 against Sr^{90} and Libby's (49) build-up factor of 11 for continued testing. The one British value mentioned above is given for comparison.

TABLE XI.—*Average maximum Sr^{90} bone equilibrium levels assuming continuation of past 5-year injection rate for 100 years*

Basis of estimate and area	Average maximum equilibrium bone level	
	Fall 1956 ($\mu\mu c$/g Ca)	In 100 year [1] ($\mu\mu c$/g Ca)
United States:

World average:		
This report, ecological data	1.3	14
This report, bone data	.9	10
Kulp (24), ecological data (1970)	1.3	14

[1] Based on, or 5MT of fission yield per year assuming testing for infinite time, an equilibrium level, with continued testing, of 11 times the present level.
[2] Libby's estimate (10) was 5 to 20 $\mu\mu c$/g Ca.
[3] Assuming an ecological discrimination factor of 10 against Sr^{90}.
[4] This value corresponds to a buildup factor of about 30.

The discrepancy between the British value and the others is immediately apparent. No details as to the basis of their estimate were given but it is possible that no consideration was given to the ratio of rates of stratospheric and tropospheric injection, since it compares favorably with the value that would be predicted from the derivations made by Campbell (5).

The data in Table XI (excluding the British value) suggest that, continued biospheric contamination at the present rate for 100 years might result in average maximum equilibrium bone levels of about 30, 25 and 12 $\mu\mu c$ Sr^{90}/g Ca for the United States, the area between 60°N–10°N latitude and the world, respectively.[8]

[7] R. K. Zeigler of LASL Theoretical Division has confirmed the calculation using Libby's assumptions.
[8] If Machta's concept of uneven stratospheric fallout is indeed the case, the average Sr 90 values for the United States and the area between 60° N–10° N latitude may be increased by about a factor of 2.

The upper limit that might be expected in the United States, assuming a factor of 5 as adequate to make allowances for non-homogeneities of Sr^{90} deposition and uptake, would approach about 150$\mu\mu$c Sr^{90}/g Ca, or 150 percent of the accepted maximum permissible level. After 30 years of testing, average maximum equilibrium bone levels may approach one-half of the above values, which may result in an upper limit for the United States of about 75 percent of the maximum allowable level. Assuming the average yearly injection of fission products during the past five years equal to about 10MT of fission yield, it would seem that the testing of 10MT of fission per year by all nations for 30 years should probably be considered the upper limit, or 5MT of fission yield per year assuming testing for infinite time. If these are the limits of acceptable injection rate, international agreement not to exceed these levels seems desirable. Present levels of Sr^{90} contamination are due almost entirely to tests held by only two nations. Present and predicted future Sr^{90} levels, even if weapons tests are continued at the present rate for a few years, does not seem dangerous. However, indiscriminate testing of high-fission yield weapons by many nations could result in serious levels of worldwide contamination.

SUMMARY

What does the accompanying mass of technical data mean with regard to the controversy over cessation or continuation of nuclear weapons tests? Nowhere in this report has a recommendation been made either to stop or to continue testing. Such a recommendation requires a careful weighing of the importance of the nation's nuclear weapons capability in averting a nuclear war, against the probability that a few people might get leukemia or bone sarcoma or manifest a genetic abnormality who otherwise might not have done so. Therefore, the decision to stop or continue tests requires a value judgment involving knowledge of the potential seriousness of present and future threats to the national security, and whether they should or should no be stopped on the basis of moral and humanitarian principles is not readily amenable to solution by the scientific method.

The purpose of this report is to evaluate, as factually as possible from existing data, the potential hazard of Sr^{90} fallout. Evaluation of existing data supports the following general conclusions:

(1) Radioactive isotopes deposited in the bone in sufficient quantity will produce serious consequences, including bone cancer and leukemia. Present Sr^{90} levels in the bones of the population are quite low. The present average maximum equilibrium Sr^{90} radiation dose to the bones of young children is greater than that for adults and is about 2 per cent of the average dose received from unavoidable natural background radiation contributed by cosmic rays and by radium, thorium, uranium, etc., in the environment. It is about 2 per cent of the maximum permissible level adopted by the National and International Commissions on Radiological Protection as acceptable for large segments of the general population. The present Sr^{90} radiation dose to adults, averaged over the total skeleton, is about one-tenth of that to children. Because of nonuniformity of fallout and individual variations in uptake and deposition of Sr^{90} in bone, a very small number of people may accumulate a skeletal dose that will be about five times the average, and an equal number will accumulate only about one-fifth the average. Since in the stratosphere there is still some Sr^{90} from past weapons tests, the average radiation dose may continue to rise until about 1975 even if no more weapons tests are held. At that time the equilibrium level may be 3 to 4 per cent of the average natural background.

(2) If Sr^{90} contamination from weapons testing by all nations continues at the same rate as has occurred during the past five years (about 10 megaton equivalents of TNT fission yield per year), equilibrium will be reached in about 100 years. At equilibrium the amount of Sr^{90} which will disappear each year from our environment due to radioactive decay will just about equal the amount that is being produced each year. At this time continuing weapons tests will not result in any further increase in Sr^{90} in the bones of the population. Assuming a buildup factor of 11 for equilibrium levels, the average Sr^{90} radiation dose to the bones of the population of the United States is predicted to be about 30 percent of the average radiation dose from natural background, or about 30 percent of the maximum permissible level adopted by the National and International Commissions. Since a factor of 5 may be necessary to allow for nonuniformities in fallout and bone uptake, the Sr^{90} radiation dose to a few individuals may approach 150 per cent of the recommended maximum level as an upper limit. If strato-

spheric fallout is not as uniform as predicted by the Libby model, the above values may be somewhat higher. Thirty years of testing will result in an average Sr^{90} level of about one-half of the equilibrium value, which may result in a few people approaching 75 percent of the recommended maximum permissible radiation dose. On this basis, limitation of biospheric contamination by all nations to about 10 megaton equivalents of fission yield per year for 30 years, or 5 megaton equivalents per year, indefinitely, might be desirable.

(3) The existing data support the conclusion that the present rate of biospheric Sr^{90} contamination, if continued for 20 to 30 years, will not produce average maximum population bone levels that will exceed the maximum permissible levels accepted by the National and International Commissions on Radiological Protection. The data also show that many nations cannot test high fission yield weapons indiscriminately and indefinitely without running the risk of seriously exceeding these recommended levels. For this reason, international agreement to limit testing might be desirable while negotiating for agreement to stop testing altogether.

(4) The data presently available definitely show that the greatest question concerning world-wide Sr^{90} contamination concerns the decision as to the *ACCEPTABLE* maximum permissible body dose for the general population in terms of the individual and in terms of world health. The answer to this question involves moral and humanitarian principles, as well as scientific uncertainties as to the biological consequences.

Some deductions as to the worst biological consequences of Sr^{90} fallout (which excludes the genetics question) can be made by accepting two rather pessimistic assumptions, neither of which has been proved, but both of which seem conservative. The natural yearly incidence of leukemia in the United States is about six cases per 100,000 population, and the incidence of bone tumors is about two cases per 100,000. Therefore, normally there are about 10,000 cases of leukemia in the United States per year and about 3,000 cases of bone tumors. This was the natural incidence even before any radioactive fallout had occurred; so atomic bombs have had nothing to do with it. The first assumption is that any amount of radiation has a small chance of producing tumors and leukemia. That is, the assumption is made that there is no *absolutely safe* radiation dose and any amount is theoretically bad. This assumption is open to serious question and is one of the major points of disagreement among scientists. If all radiation is bad, the natural background radiation which we cannot avoid must be responsible for a fraction of the six leukemia cases and the two bone cancer cases per 100,000 that occur in the population. The second assumption is that about 10 percent of the normal incidence of bone tumors and leukemia is due to natural background radiation. There is some scientific evidence from X and gamma radiation in support of this assumption as applied to incidence of leukemia, but none for Sr^{90} radiation. There is no evidence to support its application to bone cancer. We do know, however, that there are things in our environment other than radiation which will cause bone cancer; so it certainly would not be right to attribute 100 per cent of the bone cancer incidence to natural background.

On the basis of the assumptions given above, the incidence of leukemia in the United States might increase from 10,000 cases per year to about 10,030 and the incidence of bone cancer might increase from about 3,000 to about 3,010. This suggests a total increase of 40 cases out of a population of 165 million people as the maximum biological consequence of Sr^{90} fallout from weapons tested to date *by all nations*. If the present rate of biospheric Sr^{90} contamination continues for 30 years, the biological consequence of Sr^{90} fallout may be a total increase in the United States population of about 250 cases per year of these two diseases. There is a good chance that this prediction may overestimate the population risk. The assumption that even the smallest amount of Sr^{90} deposited in bone carries a small probability of harm is seriously questioned, and there is a possibility that a threshold below which no leukemia and bone cancer will be produced does exist. Animal experiments with radioactive strontium definitely indicate that Sr^{90} may not be as bad as anticipated for producing leukemia because the beta radiation from the Sr^{90} gets absorbed in the hard bone and does not radiate the bone marrow where leukemia begins. These same experiments do suggest that production of bone tumors by Sr^{90} is about as expected on the basis of human experience with radium.

(5) The present data also indicate that much more research on both the physical and biological factors of fallout must be done if weapons tests are to be continued. This research is necessary to narrow the limits of error and uncertainty in existing data and to permit predictions to be based on facts instead of on what appears to be reasonable assumptions. More research on the biological and

medical effects of radiation and radioactive materials is essential, even to the future of the power reactor program which also produces Sr^{90} and other fission products.

Although present knowledge of the biological effects of radiation and radioactive materials is not all it should be to allow plunging ahead recklessly and without worry into all aspects of nuclear technology, it is adequate to dispel an attitude of gloom and doom. Radiation is not the only potential hazard man is facing as part of the price of living in a highly developed society nor is it the insurmountable one.

(Whereupon, at 12:15 p. m., Thursday, June 6, 1957, the committee adjourned, to reconvene at 10 a. m., tomorrow, Friday, June 7, 1957, in the old Supreme Court chamber, the Capitol.)

THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN

FRIDAY, JUNE 7, 1957

CONGRESS OF THE UNITED STATES,
SPECIAL SUBCOMMITTEE ON RADIATION
OF THE JOINT COMMITTEE ON ATOMIC ENERGY,
Washington, D. C.

The special subcommittee met, pursuant to recess, at 10 a. m., in room P–63, the Capitol, Hon. Chet Holifield (chairman of the subcommittee) presiding.

Present: Representatives Holifield, Durham (chairman of the Joint Committee), Cole, Price, Van Zandt; Senators Anderson and Jackson.

Also present: Professional staff members: James T. Ramey, executive director; George E. Brown, Jr., Hal Hollister, staff technical adviser, and Paul C. Tompkins, consultant.

Representative HOLIFIELD. The committee will come to order.

The Chair would like to explain something which occurred yesterday for the benefit particularly of the press.

Dr. Libby in response to a request of mine on a previous day handed in a short statement regarding the scientific reasons for testing weapons. Shortly after this, one copy which was handed to me was turned in, I was called to another meeting, and I had to stay in it all morning, because it was an executive session. Senator Anderson took over the chair. There was some confusion between Senator Anderson and me, and neither one of us read the statement of Dr. Libby at that time or before adjournment, I should say. As there were no other copies handed out, there were some reporters, apparently, who noticed it and asked to see it. They read it before the papers were taken to the committee room. I have asked the staff to prepare some copies which have been handed out this morning, and I am going to ask, since it is a short statement—and it was not accepted officially—Dr. Dunham to read this into the record at this time.

STATEMENT OF DR. WILLARD F. LIBBY, UNITED STATES ATOMIC ENERGY COMMISSIONER, READ BY DR. CHARLES L. DUNHAM

Dr. DUNHAM (reading):

I have been asked by the committee to explain briefly in my statement for insertion in the record why I believe nuclear tests must continue.

For the survival of our Nation and that of the free world, heavy reliance is placed on the United States' defensive and deterrent capabilities. These capabilities are inextricably bound to our nuclear warheads and to the weapons systems which would carry these warheads.

We are today in a period of radical transition in the weapons systems available and becoming available. A very few years ago the possibility of a surprise nuclear attack upon the United States and the other free nations was small. Our own weapons could be readied carefully and the carrying vehicles could take time in delivering the warheads to destination.

Now, however, with the gains made by nations in delivery systems the technical possibility of surprise attack against us has increased. This then is forcing a change in our defensive systems. We require new weapons of smaller size, capable of withstanding extreme conditions, instantly ready and tailored to give the desired effect. These characteristics are particularly important and stringent in the case of weapons for defense of our Nation and our forces against possible enemy attack. Generally at present, each new weapon-delivery system requires a new or modified warhead design.

Naturally, in view of the reliance we must place on our nuclear-weapons systems, new or modified weapons and design changes must be tested if we are to rely on them in the emergency. Unfortunately, there is no substitute for testing to determine the reliability of a weapon, conventional or atomic. To cut off testing, therefore, means the cutting off of the introduction of improved nuclear-weapons systems. Though there can be very limited extrapolation of present information without testing, cessation of tests would, to all intents and purposes, end shortly our developmental work. It would mean the cutting off of attempts to achieve further improved designs—designs which would lessen still further radioactive contamination from detonations, designs to make most efficient use of materials, designs which could function under the extremes that tney would be called upon to face. It would mean that systems being developed aand urgently needed for our defense would be without the most effective warheads.

As you know, one cannot enumerate in an unclassified statement and without divulging to the world the status of our nuclear armaments the known defense and deterrent weapon systems which we would forego by stopping tests. From past test series, we have found, sometimes unexpectedly, means of increasing the efficient use of materials, reducing the size and complexity of warheads, increasing their deliverability and yield, and reducing the radioactive contamination from our larger yield devices. The committee is familiar with these past developments and with the fact that additional systems now scheduled could not be brought into being without further tests. In a public statement, I can only emphasize that our weapons development would be crippled by a cessation of tests.

Naturally, should we interrupt our testing and others do not so do, we could find ourselves shortly with systems whose nuclear warheads were not adequate for the intended purposes. With the rapidity with which weapons systems are now changing we might find ourselves in such a position in a relatively short period of time.

As I stated earlier, therefore, cessation or interruption of testing is in itself a form of disarmament. Such a step should only be taken, therefore, as a part of a comprehensive disarmament plan. It should only be taken when there are means in existence of assuring that other nations similarly will cease their testing and hence their development of new systems.

We must continue our efforts to find an assured way of disarmament, as part of which all would stop testing of nuclear weapons. In the meantime, we as a Nation should continue to limit our test shots to those essential to our development program for the weapons so vital—in the absence of safeguarded disarmament—to assuring the survival of the free world. We should continue by all possible means our efforts to reduce the amount of residual contamination from these fully justified shots.

Representative HOLIFIELD. The request of the Chair was that Dr. Libby give the scientific reasons for the continued testing of weapons. While there are some scientific reasons in the statement, there are also statements of policy and conclusions on Dr. Libby's part. In view of the fact that Dr. Libby is not here, I have no questions on the statement. Do the other members of the committee have any questions?

Chairman DURHAM. No.

Representative COLE. Except to point out, as I am sure the Chair will agree, that Dr. Libby could not discuss the scientific considera-

tions and justifications of continuing weapons tests without disclosing vital security information.

Representative HOLIFIELD. I certainly agree with that statement.

Dr. Dunham, I believe you have some documents to insert in the record.

Dr. DUNHAM. Yes; I have two statements prepared by Dr. Libby, advance copies of which the committee already has, but these are up-dated material on radioactive fallout on soils and the radioactivity of rain, and the other statement has to do with natural occurrence of radioactivities.

I would like to on Dr. Libby's behalf introduce these in the record.

Representative HOLIFIELD. I do not believe the members have had a chance to see these statements. Did you present the copies this morning?

Dr. DUNHAM. I believe Mr. Hollister has copies of these. Yes; they were brought up this morning.

Representative HOLIFIELD. For the present we will accept them without knowing exactly what they are.

Dr. DUNHAM. I would also like to take the opportunity at this time to introduce a statement prepared by Dr. Harry Wexler, of the Weather Bureau, entitled, "Radioactive Fallout in the Stratosphere," which is essentially a discussion of research approaches in meteorology to solving some of the fallout problems.

Chairman DURHAM. Mr. Chairman, this is a very interesting statement. It will not take but a few minutes to read it. Would you like to read it?

Dr. DUNHAM. I will be very happy to read it if the committee so desires.

STATEMENT OF DR. HARRY WEXLER,[1] DIRECTOR OF METEOROLOGICAL RESEARCH, UNITED STATES WEATHER BUREAU (READ BY DR. CHARLES L. DUNHAM)

Since the large nuclear explosions deposit a considerable portion of their radioactive debris in the stratosphere, these questions arise: What happens to this radioactivity? Does it mix uniformly over the world after a year or two? Is there much vertical mixing upward and downward? Are there important

[1] Chief scientist of the USNC-IGY Antarctic Program and is responsible for its entire scientific effort to be undertaken in 1957 and 1958 in Antarctica. He is a member of the USNC-IGY Antarctic Committee, the USNC-IGY Technical Panel on Meteorology, the ad hoc Arctic Committee and the ad hoc Equatorial Committee. He is a member of the United States National Committee for the International Geophysical Year and an alternate member of its Executive Committee. Received his B. S. degree in mathematics from Harvard University in 1932. He did graduate work at the Massachusetts Institute of Technology from 1932 to 1934 and from 1937 to 1938 and obtained his Sc. D. in meteorology in 1939. During the intervening period, 1934 to 1937, he worked at the United States Weather Bureau in Chicago, Ill., and Washington, D. C. He was appointed assistant professor of meteorology at the Institute of Meteorology of the University of Chicago in 1940 and left this position in late 1941 to return to defense work at the Weather Bureau in Washington. In November 1942, he joined the Army Air Force's Weather Service as a captain and was appointed senior instructor in meteorology to the Army Air Force Aviation Cadet School in Grand Rapids, Mich. While there he served as a member of the wartime University Meteorological Committee established to assist the military services in matters related to meteorological training.

In late 1943, Dr. Wexler was transferred to the Weather Division of the Army Air Forces in Washington, where he served as research executive and initiated and fostered a program of research in weather which later developed into the large Air Force program in geophysics. In September 1944, with Colonel Floyd Wood as pilot, made the first penetration of an Atlantic hurricane, which because of its unusual intensity became known as the Great Atlantic Hurricane. In 1946 Dr. Wexler became Chief of the United States Weather Bureau's Science Services Division. In 1955 he was named Director of Meteoro-

seasonal and geographic effects? Are there channels connecting the stratosphere to the troposphere through which large quantities of radioactvity can flow downward with the air and ultimately reach the precipitation layers and thus be rained out?

Dr. Machta has presented testimony pointing strongly in the direction of nonuniformity of stratospheric fallout which is corroborated by analysis of strontim 90 in soil samples collected by Dr. Alexander. This is a surprising result to most meteorologists who would believe that after a year or two, airborne contaminants released in the stratosphere should be uniformly mixed over the world. Admittedly, there has been little evidence to go on; for example, Krakatao volcanic ash apparently spread uniformly over the world within 3 to 6 months as best as could be judged from fragmentary optical and solar radiation effects available in 1883.

In recent years, observations of the atmospheric content of ozone, most of which is found in the lower stratosphere, show decided geographic and seasonal nonuniformity over the world, although the interpretation of this gas in terms of mixing is complicated by geographic and time variations in solar ultraviolet radiation, air temperature, and large-scale vertical air motions.

Against this background of conflicting evidence, one thing stands out. In view of great quantities of radioactive debris now present in the stratosphere and the possibility that as the years go on, new and larger amounts may be placed there, we must learn much more about the lateral and vertical transport and mixing mechanisms in the stratosphere. In addition, further understanding of atmospheric removal processes is needed. An outline of proposed research and development is presented below.

1. METEOROLOGICAL OBSERVATIONS IN THE STRATOSPHERE

Only in recent years have meteorological balloons penetrated systematically into the lowest layers of the stratosphere—but their average height (60,000 feet) is well below the top of the large thermonuclear bomb mushroom clouds (100,000 feet or higher). With increased effort during the International Geophysical Year, the average height may approach closer to 100,000 feet, but there will be large areas, particularly in regions of low temperatures, where the balloons become brittle and burst before rising appreciably in the stratosphere or even reaching the stratosphere.

Recommendation: Development of a relatively inexpensive, lightweight, solid propellant, frangible cased rocket, capable of carrying meteorological instruments to 200,000 feet and dropping them by parachute which can be followed by radar. This offers the only hope of establishing a widespread network of meteorological observations in the important 100,000–200,000 foot layer to observe stratospheric winds, temperatures and densities, so that the higher yield atomic clouds can be tracked.

2. AIR SAMPLING AND ASSAYING IN THE STRATOSPHERE

Although the availability of stratospheric meteorological observations will aid in determining the bulk transport of clouds of radioactive debris, they will not usually be sufficient to help estimate the degree of mixing between the

---

Footnote continued from preceding page.

logical Research. The Weather Bureau has made Dr. Wexler available to the USNC–IGY for scientific direction of the Antarctic program.

In 1945 the Institute of Aeronautical Sciences presented Dr. Wexler the Losey Award in recognition of his outstanding contributions to the science of meteorology as applied to aeronautics.

A member of the Advisory Committee on Reactor Safeguards for the Atomic Energy Commission; Chairman, Committee on the Meteorological Aspects of the Effects of Atomic Radiation of the National Academy of Sciences; a member of the Meteorological Operations Subcommittee of the National Advisory Committee for Aeronautics. He is a councillor of the American Meteorological Society, a fellow of the American Academy of Arts and Sciences, a member of the Royal Meteorological Society and the Washington Academy of Sciences. He is a member of the American Geophysical Union. In August 1955, Dr. Wexler was a member of the United States delegation to the Atoms for Peace Conference in Geneva, Switzerland.

As an internationally recognized authority on meteorology, Dr. Waxler has published some 50 papers in scientific journals treating such subjects as the radiative cooling of the air, polar anticyclones, atmospheric turbidity, structure of hurricanes, and upper atmosphere temperatures and dynamic connections with the lower atmosphere.

In November 1956 was the recipient of the Department of the Air Force Exceptional Service Award in recognition of distinguished patriotic service. (Submitted by U. S. Department of Commerce.)

radioactive clouds and their environments. The existing limited program of sampling the stratosphere for natural and artificial constituents has thrown some light on the incompleteness of mixing in the stratosphere. Strontium 90, carbon 14, water vapor, and ozone have been sampled or assayed directly, and the few observations available, especially of the vertical profile of water vapor and ozone, reveal a marked stratification in the lower stratosphere, indicating very weak vertical mixing—at least during the few times soundings were made. There are not sufficient observations geographically or seasonally to arrive at similar conclusions regarding the degree of lateral mixing.

Recommendations: An intensified program of air sampling and analyzing to a height of 150,000 feet by aid of large "sky-hook" balloons should be inaugurated over large areas to determine the lateral and vertical mixing efficiency of the lower stratosphere and exchange mechanisms with the troposphere.

3. PREDICTION OF STRATOSPHERIC TRANSPORT AND MIXING

After an adequate program of stratospheric observations has been inaugurated so that one has a reasonably accurate picture of the present state of the stratosphere and its distribution of trace elements, then the question of the future state arises.

The few day-to-day weather analyses that have been carried on in the lower stratosphere suggest strongly that the flow patterns are so different from those existing below that inference or extrapolation from lower level happenings or predictions are of little or no value. The electric computer, with its capacity for analyzing large quantities of data quickly, has proved its value in forecasting important changes in flow pattern in the troposphere such as the change from a basically zonal (west and east) flow to largely meridional (north and south) flow. Such changes, occurring very rapidly, can have an important effect on the distribution of airborne material in the troposphere. It is suspected that there may be similar large scale changes in flow patterns in the stratosphere.

Recommendations: A special research unit should be established to plot and analyze daily stratospheric charts, using all the data described above, and having access to a modern high speed automatic computer to develop prediction techniques for stratosphere transport, mixing, and exchange with the troposphere.

4. REMOVAL PROCESSES

The hazard from strontium 90 stems from ingestion. The radioactive particles must, therefore, be removed from the atmosphere onto the ground or foliage. Evidence suggests precipitation as the prime removal process, although not the exclusive one. Impaction on obstacles and, to a lesser extent, gravitational settling are other known mechanisms.

The details of the precipitation scavenging process are a matter of speculation. Empirical correlations with fallout are inadequate for predictive purposes under different conditions.

The removal of small particles over water bodies is especially important since water surface constitutes almost three-fourths of the earth's surface.

Recommendations: The study of removal processes by impaction, scavenging, etc., should be intensified. Ocean samples should be analyzed for strontium 90 and cesium 137 in order to determine whether the oceanic fallout pattern follows that over land.

Representative HOLIFIELD. Are there any questions on this statement?

Dr. Dunham, does the AEC have any comments on this statement?

Dr. DUNHAM. No, it seems like a very sound recommendation.

Chairman DURHAM. You have made some fine recommendations here. Are we equipped to carry out the recommendations, as far as you know?

Dr. DUNHAM. Maybe Dr. Machta, who is here, would like to speak to that point. I gather his item 1 would require some development work. I am sure Dr. Machta is better prepared to answer that question.

Representative HOLIFIELD. Dr. Machta, would you like to come forward?

Chairman DURHAM. Have you read Dr. Wexler's statement?

Dr. MACHTA. Yes, I have.

Chairman DURHAM. Do you concur in his recommendations?

Dr. MACHTA. Yes, sir, I do.

Chairman DURHAM. Is any agency of the Government equipped to carry out his recommendations at the present time?

Dr. MACHTA. Yes, I think the Weather Bureau, if asked to do so, would be equipped to do it.

Chairman DURHAM. You are qualified to do it?

Dr. MACHTA. Yes, sir. We have a high-speed computer which is used for our everyday forecasting which would be devoted to this purpose, and we have in mind certain other projects which Dr. Wexler indicated.

Chairman DURHAM. You think it is important that we proceed to do this type of testing?

Dr. MACHTA. Yes, sir; I do.

Representative HOLIFIELD. This statement, as I read it, has to do with nonuniformity of stratospheric fallout. Does that pertain to the matter while it is in the stratosphere or does it pertain to the nonuniformity of its descent to earth?

Dr. MACHTA. The statement includes both aspects. In making a prediction, one must know where it is in the atmosphere, and how it would be removed.

Representative HOLIFIELD. At the present time the research you recommend is to find out the conditions in the upper stratosphere?

Dr. MACHTA. This primarily, but secondly the removal processes. For example, does it, as we really suspect happens, come down primarily in rainfall and factors of this sort?

Representative HOLIFIELD. It goes to sustain the theory of nonuniformity of deposit on the earth's crust, does it not?

Dr. MACHTA. I do not believe I would say that. What we want to do is to conduct more research to confirm the suspicions we have.

Representative HOLIFIELD. His suspicions, if you want to call them that, are along that line?

Dr. MACHTA. Yes, sir.

Chairman DURHAM. Is any of this type of sampling now being done?

Dr. MACHTA. Yes. During the International Geophysical Year, a very much more extensive program of ozone sampling in the upper atmosphere is to be conducted. We believe this will throw great light on the exchange in the stratosphere and the exchange between the stratosphere and troposphere. In addition, the AEC is undertaking a very good sampling program of strontium 90 and other fission products in the stratosphere which would be very important.

Chairman DURHAM. How about the oceanic testing?

Dr. MACHTA. According to my information, the Woods Hole Oceanographic Institute is sampling the Atlantic Ocean to determine the content of strontium 90. Their preliminary report will be out very shortly.

Representative HOLIFIELD. Before we proceed further, it has been called to my attention that we have Dr. Waterman, the Director of

the National Science Foundation, present this morning to partake in the panel discussion. We are glad to have you here, sir.

Dr. WATERMAN. Thank you.

Representative HOLIFIELD. Dr. Dunham, yesterday Senator Richard L. Neuberger released a press release which reads as follows:

Senator Richard L. Neuberger today urged that the Atomic Energy Commission make public a report on strontium 90 effects submitted to the AEC by an advisory committee.

The Oregon Senator charged in a Senate speech that the report, requested by the Commission over 2 years ago, has not yet been issued in final form due to "official reluctance."

Dr. H. Bentley Glass, professor of biology at Johns Hopkins University, indicated Tuesday that release of the study prepared by the Advisory Committee on Biology and Medicine has been delayed by the AEC. Glass is a member of the advisory group.

"The American public has a right to know of the dangers inherent in exposure to radioactive materials," Neuberger declared. "Suppression of this report on the part of the Atomic Energy Commission represents a betrayal of public trust."

"This subject is one of vital concern to all Americans," the Senator said. "It affects not only the present population of the United States, but future generations as well. Any attempt to shield the facts from public scrutiny is inexcusable."

The 44-year-old Oregon Senator, sponsor of a bill to establish a National Radiation Health Institute, said that the AEC owes the public an explanation as to why the report was not previously released. "Full disclosure of unclassified information regarding radiation exposure is vital to establishment of informed public opinion and the rational discussion of this issue which looms paramount in the minds of many Americans" he said.

In view of the fact that this release was made during these hearings, and in view of the fact that there has been no evidence presented to the committee that there has been such a study or report, I will ask you at this time to comment on this in order that the Atomic Energy Commission may have an opportunity to state its views.

Dr. DUNHAM. Thank you very much, Mr. Holifield.

First I would like to make it perfectly clear that there is no such report. The Commission has never asked that the Advisory Committee on Biology and Medicine make a report.

On the other hand, as I indicated the other day in testimony, during the last 2 years there has not been a meeting of that committee at which the matter of the fallout studies was not discussed, and a brief bringing up to date of the commitee on the facts given by a member of my staff. The committee has considered this matter very, very carefully. They have as yet prepared no statement on the subject.

Representative HOLIFIELD. There has been a study made of this subject?

Dr. DUNHAM. Not by the committee as such. They have reviewed the status of the material being developed at each of their meetings each year. When on 1 or 2 occasions I neglected to put this item on the agenda, one or another of the Commissioners called my attention to it, and asked that it be put on the agenda, bringing the committee up to date on this information.

Representative HOLIFIELD. Has this committee been presented with the results of your studies on strontium 90?

Dr. DUNHAM. Yes. They have been presented, as I say, at every meeting, and they have been brought up to date on the new material as it developed.

Representative HOLIFIELD. I am speaking of the congressional committee. Has this committee been presented with all of the pertinent information in regard to strontium 90 which is in possession of the AEC?

Dr. DUNHAM. I believe this is so. With the material introduced in the record by Dr. Libby and material presented by other people who have appeared before you, I think this constitutes the present body of knowledge of the Atomic Energy Commission on the contamination of the environment by strontium 90.

Representative HOLIFIELD. Is there an area of knowledge on the subject of strontium 90 which is in the classified area and which has been or will be presented to the committee in executive session?

Dr. DUNHAM. The only material pertinent to this question which is classified is that to do with actual fission yield of specific devices. This material, I believe, has been in the hands of the committee. You are brought up to date at each series of tests as to what these fission yields are.

Representative HOLIFIELD. So there has been no withholding of your overall calculations as to the amount that is in the stratosphere, and which has been deposited, according to your measurements, in various places throughout the earth's crust?

Dr. DUNHAM. That is right. There has been no withholding at all.

Representative HOLIFIELD. That information, to the best of our present ability to measure, has been presented not only on the continental United States, but other measurements in other lands?

Dr. DUNHAM. Yes. We have presented you with all the material we have developed.

Representative HOLIFIELD. Are there any further questions on this point?

Chairman DURHAM. Then it is a fact, Doctor, that all the information has been made public through the present hearings and other methods?

Dr. DUNHAM. That is correct, sir.

Representative HOLIFIELD. Dr. Dunham, we will now let you read your statement.

STATEMENT OF DR. CHARLES L. DUNHAM, DIRECTOR, DIVISION OF BIOLOGY AND MEDICINE, ATOMIC ENERGY COMMISSION

Dr. DUNHAM. Thank you. I would like first to say what I am going to do is to review briefly the present program of research of the Division of Biology and Medicine which relates to fallout. I understand the committee has invited representatives of other Government agencies who are making very important contributions to the general information on this subject to present their programs. Therefore, I will let them speak for themselves.

I have with me today, Dr. Shields Warren, from the New England Deaconess Hospital. I would like to call upon him, after I have finished, to speak from the standpoint of a university scientist, plus his great background in this particular area. Also, Dr. Austin Brues, who is the Director of the Division of Medicine and Biology of the Argonne National Laboratory, to speak to you from the standpoint of a director of such a program at one of our national laboratories.

That part of the research program of the Division of Biology and Medicine which relates to fallout falls into four major categories:

1. Collection and analysis of samples to determine distribution of strontium 90 in the atmosphere and the biosphere.
2. Further refinement of our knowledge of the radiotoxicity of strontium 90 and cesium 137 and other radionucleides and of the long-term effects of external gamma radiation.
3. Research into methods of treating and ameliorating radiation injury.
4. Civil effects test programs at weapons tests.

With the exception of the activities of the Health and Safety Laboratory in New York, all work is done by contract either at national laboratories or at private laboratories, both university and commercial, or with Government laboratories by transfer of funds to Naval Radiological Defense Laboratory, Naval Research Laboratory, the Air Force, and so forth.

With the exception of experimental studies done at weapons tests, none of this work is classified even at the time it is done. In fact, we have made deliberate efforts to see that this is so, so as to avoid delays in making the information available. That work undertaken at weapons tests is now carefully planned so that insofar as possible the first preliminary reports are written in unclassified form and the final complete reports whenever possible are unclassified or unclassified versions are written simultaneously.

I. COLLECTION AND ANALYSIS OF SAMPLES

The gummed-paper network of the Health and Safety Laboratory now comprises 94 stations in the United States and 75 in foreign countries. Stainless-steel pot collections are being made at 7 stations in the United States and in the following countries: Hawaii (which is not a country), Chile, French West Africa, Austria, Union of South Africa, Thailand, South Rhodesia, Peru, Pakistan, Kenya, Japan (2), Colombia, and Brazil. This network is to be expanded as cooperative arrangements are developed with other countries.

Soil sampling on a worldwide basis is under Dr. Lyle Alexander, United States Department of Agriculture, and collections in 17 countries were made in 1955 and in 39 countries in 1956 and annually or more frequently collections are made in various parts of the United States. These are supplemented by soil collections in the New York area by the Lamont Laboratories of Columbia University. In the future, we hope to be able to undertake simultaneous soil sampling in North and South America on an annual basis.

Sampling of the Pacific Ocean in relation to weapons tests is extensive, and is supplemented by excellent Japanese sampling and analysis, with frequent exchanges of data.

The ocean is large, and we cannot sample the whole ocean, but we do endeavor to follow the radioactive material as it moves along with the current. In cooperation with such organizations as the NORPAC and the Japanese, we have been able to get quite a lot of information on the movement of these water masses.

Followup studies on the Rongelap Atoll are annual, and include analysis of soils, edible plants, animals, and seafood. Both the Naval Radiological Defense Laboratory and the University of Washington

School of Applied Fisheries, and the biological laboratories established by the AEC at Eniwetok have taken part in this with assistance from the Walter Reed Medical Center. The medical followup on the people of the Rongelap and Uterik Atolls is under the direction of a group at Brookhaven National Laboratory with assistance from the National Institutes of Health, Walter Reed Medical Center, and the Department of the Navy.

The human bone sampling program is largely carried out by the Lamont Laboratories in New York City with supplementary collections by the Argonne Cancer Research Hospital and other groups in this country. Analyses are carried out by commercial laboratories with careful cross checks by Lamont Laboratories and by the Health and Safety Laboratory of AEC for analytical accuracy.

Representative HOLIFIELD. I understand that Dr. Schulert is here to talk about the bone samples.

Dr. DUNHAM. That is fine.

Stratospheric sampling: Techniques are being developed to make possible the monitoring of radioactive fission products in the stratosphere. Such measurements would provide important information on quantities of weapons debris reaching the stratosphere, the distribution and retention of such materials in the stratosphere, and their release to the lower atmosphere. In experiments now being conducted with the Department of Defense, balloons were used to carry sampling equipment to altitudes of 50,000 to 90,000 feet, where radioactive particles were filtered from a defined volume of air. Balloons were being launched at Minneapolis, Minn., San Angelo, Tex., and at France Air Force Base in the Panama Canal Zone.

Radiochemical analyses of the samples are presently being made on a pilot scale by the Commission's Health and Safety Laboratory, New York, until arrangements can be made with commercial laboratories to perform this work. Results of these studies will be useful in planning a worldwide network for the stratospheric monitoring of long-lived radioistotopes.

In addition, we have work at the Midway Laboratories in Chicago in attempting to develop a more adequate method of sampling. The present sampling devices are filter devices and, although we believe they collect 25 percent of the material present in the stratosphere, we want to be able to be sure we are actually getting all of the material from a given volume of air.

The milkshed sampling program includes regular sampling in the New York and Chicago milksheds, with less frequent sampling by the Health and Safety Laboratory and the Los Alamos Scientific Laboratory of other milk supplies.

Food sampling in the United States is related to milksheds and the location of United States agricultural experiment stations and carried out largely under Dr. Alexander in the United States Department of Agriculture.

Representative COLE. May I interrupt here, Dr. Dunham, to ask you to explain to what extent you conduct continued sampling of milk in the area of the Nevada tests?

Dr. DUNHAM. We have some samples of that.

Representative COLE. The reason for the question is that, presumably, the fallout would be greater in the area near to the Nevada test.

Dr. DUNHAM. Yes, sir.

Representative COLE. Some people may feel and I am curious why you select the Chicago and New York milksheds for your milk tests.

Dr. DUNHAM. Those are the two largest milksheds, of course. As to the milk within hundreds of miles of the Nevada test site, much of that is imported. Some is developed locally. But the Los Alamos Scientific Laboratory has been sampling milk in communities there.

Representative COLE. That answers the question. The Los Alamos Laboratory is the agency responsible for sampling the milk in the area of the Nevada test.

Dr. DUNHAM. That is correct, sir.

Representative COLE. That is, I assume, a reasonably continuous sampling process?

Dr. DUNHAM. That is correct. We are in the process of initiating a worldwide food sampling program with the assistance of the Interdepartmental Committee on Nutrition, aimed at checking especially the food constituting the principal source of calcium in the diet. Analyses will be by the Health and Safety Laboratory or contracted out.

There are two ways in which the information thus developed reaches the public: One, as unclassified Atomic Energy Commission reports, second, the publication in the scientific literature. The material often appears first as an unclassified AEC report and later is published in a scientific journal. This is in part because of backlogs of accepted papers in the better scientific journals. This material is also disseminated to the United Nations Scientific Committee on Radiation Effects as soon as it has become available in printed form to United States scientists. It is our hope that many of the worldwide collections and analyses can be done in the countries of origin. The AEC Health and Safety Laboratory is training scientists from a number of countries in these techniques. Pending their taking over, we are getting excellent cooperation from the countries which have expressed an interest in these matters. Meanwhile we are analyzing any samples submitted from foreign countries.

Representative VAN ZANDT. At this point, Dr. Dunham, is it not true that spokesmen from the AEC are constantly making speeches and copies of the speeches are given a pretty good coverage, and they contain firsthand information taken from the files of the AEC?

Dr. DUNHAM. That is one of the reasons these speeches are given. By the time you get the reports accepted and printed by the scientific journals, much time has elapsed. Many of these speeches are done deliberately to get the material out as fast as it is available.

Representative VAN ZANDT. I might say I read these speeches religiously and as a result I feel I am being kept up to date in regard to the developments in this field.

Representative COLE. Let me say in response to that that if my good friend, Mr. Van Zandt, reads all the speeches coming to his desk emanating from the Atomic Energy Commission, he does not do anything else.

Representative VAN ZANDT. I am speaking about radiation hazards.

Representative COLE. Because they come to my desk, and I admit that I do not read them all. They come too fast.

Representative VAN ZANDT. I agree with my colleague from New York. I am especially interested in the radiation hazard.

Dr. DUNHAM. I know you have a special interest in that, Congressman.

The worldwide and national bone sampling program will be stepped up as more sources of material can be found.

II. RADIOTOXICITY STUDIES

The radiotoxicity studies include extensive small animal studies at the University of Rochester atomic energy project, Argonne National Laboratory and Los Alamos Scientific Laboratory. Lifetime studies in dogs at the University of Utah to compare in mature animals radium, plutonium, mesothorium, and strontium 90 have been underway for 6 years. The University of California, Davis Campus, is just commencing a womb-to-tomb strontium 90 experiment in dogs. That means the mothers are fed strontium 90, and as soon as the pups are born, they are given strontium 90 throughout their whole lifetime. That is the way that experiment is planned.

Representative COLE. Doctor, would you tell me why dogs are selected for this experiment, rather than any other animals?

Dr. DUNHAM. Yes. We have quite a lot of information on mice and rats. But these substances we are talking about here are bone seekers. A rat bone or a mouse bone never really ceases to grow. Furthermore, they are very short-lived animals. It is a matter of a year or 2 or 3 at the most. Dogs are chosen because they are longer lived and, secondly, because their bone development and maturation follow very closely the human pattern. So when they are mature and the epiphyses have closed the bone structure of those dogs resemble exactly what we know to exist in the radium dial workers and the people who were given radium as treatment which are the basis of our information on radiotoxicity of internal emitters in man.

Representative COLE. What is mesothorium?

Dr. DUNHAM. Mesothorium is one of the products in the decay scheme of the thorium series. It is the material which Dr. Looney mentioned as being in the radium dial paint, and which has confused some of the data there because the early work was done sort of like somebody's cook. They might put more or less mesothorium in the mixture. Dr. Evans' group at Cambridge has worked very hard and now I believe has developed a method which he feels is satisfactory so he can work back on the living patients and estimate how much of the thorium series was introduced with the radium. This has been a very difficult problem.

Three more large-scale dog studies are planned with strontium 90, cesium 137, and mixed fission products.

Studies on the discrimination between strontium and calcium in animals and humans are underway at the Oak Ridge Institute of Nuclear Studies, University of Rochester, University of California at Los Angeles atomic energy project, Sloan-Kettering Research Institute, and Montefiore Hospital in New York. Additional work will be undertaken by the Argonne National Laboratory and the Argonne Cancer Research Hospital as low-level counting facilities become available at Argonne National Laboratory.

III. TREATMENT OF WHOLE BODY RADIATION INJURY AND METHODS OF AMELIORATING RADIATION EFFECT

Currently there are three approaches to a more specific treatment for whole-body injury:

1. Prophylaxis: This approach is useful only if given prior to exposure. In other words, it would have no practical value in the event of an atomic catastrophe except if a person knew he had to go in and take two or three hundred roentgens, he would be able to take some prophylactic measure to reduce his injury.

Representative VAN ZANDT. Dr. Dunham,, would it be possible to innoculate military personnel with this preventive, whose duties kept them in close proximity to reactors on board naval vessels?

Dr. DUNHAM. What we have been working with now, which shows promise, you have to take a few hours before exposure. It is questionable whether a person could take it indefinitely so I don't think it would be useful there. But if a person had to go in in the event of an accident and had to take 300 roentgens to save a person's life, this would be very useful.

Representative VAN ZANDT. What would be the life of this preventive?

Dr. DUNHAM. It can be taken in experimental animals. This is the point I want to make very definitely. This can be taken for a matter of several days. You have to begin and give a good-sized dose within a few hours prior to beginning of the exposure.

Chairman DURHAM. What is the combination of the bromide?

Dr. DUNHAM. That means that this long name here is a salt just like sodium chloride. The chloride is what makes it the salt.

Chairman DURHAM. I could not tell from that whether it was a combination of 3 or 4 other salts or not.

Dr. DUNHAM. It is the bromide of this compound.

Representative COLE. Is there reasonable reason for encouragement in this field of pretreatment?

Dr. DUNHAM. Yes. We found this particular material, which I abbreviate AET, developed at the Oak Ridge National Lab to be quite effective in essentially doubling the resistance of rats, mice, and monkeys. The only question is what is the toxicity of the material in man? We found in dogs they do not tolerate it. You cannot give enough to protect the dog and similarly the rabbit. This will have to be determined and some studies are being done. Some work is being done using this material at the National Institues of Health and other hospitals, not in the doses required to protect, but in the treatment of what is called radiation sickness, the nausea and vomiting that goes with radiation therapy, so we can begin to get a feel of how sensitive human beings are to this material.

We don't know at this point. It may be like one of the new drugs for TB. You can cure monkeys because they are 30 times less sensitive than humans to the drug. But you can't give enough to the human to totally wipe out the disease.

Representative VANZANDT. How much of the dose could the body of of the animal absorb if this preventive was applied beforehand?

Dr. DUNHAM. I don't recall the exact doses for any specific species of animals. It is a matter of a few hundred milligrams. I don't recall the exact dose.

AET (S-B-aminoethylisothiouronium bromide) pretreatment developed at Oak Ridge National Laboratory holds great promise. Its toxicity in humans has yet to be fully evaluated. In experimental animals it will roughly double resistance.

2. Treatment which is effective if given up to 48 hours after exposure begins: (*a*) Bone marrow transplants have proven very effective in a variety of mamalian species—mice, rats, and monkeys. Intensive efforts to establish the value of this treatment in humans suffering from aplastic anemia are currently underway. There are several hospitals in this country which are attempting to do this in humans who have had their bone marrow injured by radiotherapy which was necessary to treat a cancerous condition. This has only been going on for a few months. I think we will have a pretty good feel for this 6 months from now as to whether this is a feasible approach.

Representative VAN ZANDT. Dr. Dunham, some years ago at Los Alamos there was an accident that involved Dr. Graves and another physicist.

Dr. DUNHAM. Yes.

Representative VAN ZANDT. The other physicist died as a result of the dose.

Dr. DUNHAM. That is correct.

Representative VAN ZANDT. How much knowledge did the Commission gain as a result of that accident which caused the death of the physicist?

Dr. DUNHAM. I would say that the report which has been published in the Annals of Internal Medicine of both accidents—there were 2, 1 a little earlier in the game, and 1 about 1945—constitutes the most carefully documented, from a scientific standpoint, group of cases of whole body radiation exposure, complicated by skin burns, that exists anywhere.

Representative VAN ZANDT. Do you recall the name of the physicist?

Dr. DUNHAM. It was Dr. Sloton who died in one accident. The other one was an Armenian name. Dr. Sloton is the one I think you are thinking of.

Representative VAN ZANDT. How long did he live after the accident?

Dr. DUNHAM. About 3 or 4 weeks.

Representative VAN ZANDT. Can you describe the body reaction to the exposure?

Dr. DUNHAM. What essentially happened is that he had his hands quite close to the criticality experiment that got out of control, so he received probably 60,000 to 80,000, or better, rep equivalent to the skin and forearms. He received a very extensive burn. It was almost as though you immersed his hands in a tub of boiling water and held them there for some time. In addition there was a complete cessation of the formation of all the blood constituents. That was the whole body effect of the mixed gamma and neutron irradiation.

Representative VAN ZANDT. Was he unconscious immediately after the accident?

Dr. DUNHAM. I don't recall. I don't think anybody was unconscious immediately after the accident.

Representative VAN ZANDT. I understand there was ample time to study the effects?

Mr. DUNHAM. These were done by Dr. Louis Hempelmann, who is now at Rochester. I might say that this matter of bone-marrow

transplants was originally developed by Dr. Lorenz, the late Dr. Lorenz, at the National Cancer Institute, who was working during the Manhattan District days very closely with Dr. Leon Jacobson at the Argonne National Laboratory.

(b) Another approach is to concentrate an active substance believed to be present in pregnant cow's blood. This is a very elusive material and all attempts to concentrate it to date have failed. It is fragile and very difficult to keep in its original state. There is no question that there is something in pregnant cow's blood which does convey a certain degree of protection after injury has occurred.

III. REMOVAL OF RADIONUCLIDES FROM THE BODY

As to the removal of radionuclides from the body, and this is of prime interest with respect to fallout and strontium 90, whereas we now have two very valuable drugs, EDTA (ethylenediamine-tetraacetic acid) and zirconium citrate which will divert plutonium in the blood stream away from bone and into the urine. No known preparation will do this for strontium. We have nothing which will selectively remove important amounts of either plutonium or strontium once it is deposited in the bone. Work in this field has been discouraging; nevertheless scientists at the Los Alamos Scientific Laboratory and at the Montefiore Hospital in New York are working hard at the problem.

We have a few projects studying skin burns induced by beta radiation as well as the followup studies on the Sandstone skin burns, and the skin burns in the Rongelapese. There are also a series of studies dealing with the problem of inhalation of radioactive materials. In addition to all this we have a large effort in the genetic effects of radiation and in the biochemical effects of radiation which will provide basic knowledge of the mechanisms of injury which in turn should permit a more efficient approach to the problem of combating radiation effects.

IV. CIVIL DEFENSE ASPECTS

As to the methods of coping with fallout, they fall into two groups.

1. Adequate shelter during maximum gamma radiation hazards: The Division of Biology and Medicine has, since 1952, taken advantage of each Nevada test series to develop information on shelter design. This work is done in cooperation with the Federal Civil Defense Administration and at Operation Plumbob the FCDA is supporting practically all of the work on shelters.

2. Decontamination: This is relatively easy with ordinary detergents and water for small objects and structures. For larger areas it is an economic problem. One approach is to fix with asphalt spray, then bulldoze off. For very large farm areas this becomes very difficult and one must rely on time for decay and deep plowing for more uniform mixing, thus diluting available strontium-90. Small areas of low-calcium soil can be treated with calcium to reduce the strontium-90–calcium ratio. Milk can be treated similarly up to a point, or one can simply remove all calcium and strontium by ion exchange resins and add uncontaminated calcium. Continuing the initial studies at Upshot-Knothole and at Operation Teapot, Operation Plumbob will develop further information on contamination of soils, crops,

and foods, shielding attenuation factors for various structures and structural configurations, and evaluation of decontamination procedures under field conditions.

Mr. Chairman, at this point I would like to ask permission to introduce into the record a summary of the Operation Plumbob civil effects test group project summaries, dated 1957. I would like also, with your permission, to introduce into the record a letter which I wrote you on May 28 outlining the shelter program at Operation Plumbob.

Representative HOLIFIELD. I am glad you are presenting that. I had intended to ask you to, or have Mr. Corsbie do so.

(The material referred to follows:)

MAY 28, 1957.

Hon. CHET HOLIFIELD,
Chairman of the Special Subcommittee on Radiation of the Joint Committee on Atomic Energy,
Washington, D. C.

DEAR MR. HOLIFIELD: This is in reply to your request of May 27, 1957, for information on the number of shelters, and sponsors thereof, being tested in the current weapons-test series.

The program of the civil effects test group includes studies on the blast effect on prototype shelters and test structures, the latter being tested principally to obtain engineering design data. There are 3 reinforced home-type shelters for a few persons; 1 mass shelter capable of holding large numbers of people and serving the dual function of a parking garage; 3 concrete dome structures for obtaining engineering design data; 1 industry-financed prototype vault for records storage; 1 industry-financed windowless reinforced clay-masonry structure; 9 shelters similar to design and capacity of the German structures; and 3 prototype entranceways to test blast-resistant doors, ventilation equipment, et cetera, for France.

All of the above structures are being tested under the sponsorship of the Federal Civil Defense Administration and, except for the industry-sponsored and foreign shelters, are being financed by FCDA.

In addition, the AEC is continuing some blast biology studies, using two shelters which were included in the Teapot series of 1955. These were tested at pressures of approximately 100 pounds per square inch. They are being used to supply further data on biologically acceptable criteria for open shelters.

Also, I am enclosing copy of Mr. Corsbie's remarks prepared for the press briefing in Nevada, which explains in more detail the civil effects test program.

Sincerely yours,

C. L. DUNHAM, M. D.,
Director, Division of Biology and Medicine.

[Preseries briefing, May 1957]

NEVADA TEST ORGANIZATION

OFFICE OF TEST INFORMATION

Las Vegas, Nev.

REMARKS BY ROBERT L. CORSBIE, DIRECTOR, CIVIL EFFECTS TEST GROUP

Organizationally, the Civil Effects Test Group is one of six scientific and technical units reporting to the test director and is a counterpart of the Military Effects Group. It is principally sponsored by AEC and FCDA. Other Government agencies, some private industrial groups, and two foreign nations have projects in this program. The foreign nation and industry projects are proposed and sponsored by FCDA. There are financial arrangements between the participants and the Civil Defense Administration.

The scientific and technical content comprises 10 programs, 54 projects, about 200 shot participations, and requires at NTS a peak population of around 400 scientific and staff personnel over the operational period of several months.

All projects are reviewed by the appropriate scientific and technical test screening and planning committees before acceptance for field testing, and are coordinated with the military effects tests.

The continuing need for effects information parallels and keeps pace with new developments in weapons. The civil effects program stems from this continuing need for up-to-date information on the weapons effects given by a family of nuclear weapons. Our weapons development tests afford an opportunity to augment laboratory experiments with new and useful knowledge from nuclear detonations. Continental tests afford unusually good opportunities to verify in the field various theoretical concepts and laboratory programs which are directed toward complete knowledge of effects on man.

The six general areas of study in the Plumbbob program are as follows:

1. Fallout radiation
2. Prompt-gamma and prompt-neutron radiation
3. Blast effects on structures
4. Blast biology studies
5. Radiological countermeasures and training
6. Instrumentation and supporting services

FALLOUT STUDIES

The fallout studies for Plumbbob represent a continuation of work begun by the Atomic Energy Project of UCLA in the study of the fallout from the Trinity test in 1945. The main purposes of these studies include:

(*a*) Learning to control the availability of radioactive fallout to plants, animals and man;

(*b*) Defining accurately the limits of environmental radiation that can be safely tolerated. Such studies are indispensable also for establishing safety criteria for weapons testing program.

PROMPT-GAMMA AND PROMPT-NEUTRON RADIATION STUDIES

It is necessary to study prompt-neutron and prompt-gamma radiation to obtain data on shielding necessary for shelter design. Better understanding of biological effects of radiation is possible through the advances in gamma and neutron dosimetry. Radiation dosimetry now available makes it possible to measure radiation doses in the field with an accuracy which equals or exceeds measurements in the laboratory. Laboratory and field experiments relating to radiation effects on animals have pointed up the necessity for a better-defined relation between biological effects on animals and on humans. This has reemphasized the value and foresightedness of the medical studies through the Atomic Bomb Casualty Commission that have been underway in Japan since 1946. The ABCC files contain clinical records of more than 4,000 well-documented cases of survivors. These afford data which would be more meaningful to all radiation medicine in the world if we knew the varying doses that individual cases received under the known shielding conditions and distances that prevailed.

During Operation Plumbbob we will initiate studies that are expected to establish the angular distribution of radiations at several distances in air so that total effect on persons inside structures can be evaluated. These basic data will permit the next phase of a long-range program to begin. This will be the determination of the attenuation and scattering by structural and other shielding materials, including terrain. Around 65 percent of the survivors whose cases are adequately documented were shielded in light wood houses of unique construction and geometry, and it is therefore necessary and important that these materials and geometrical configurations be studied to evaluate the shielding afforded to individuals in such structures.

The results of the Plumbbob studies, plus subsequent pilot and laboratory experiments, will permit detailed planning for a third phase of the overall program, the end-product of which is expected to establish the individual doses in terms of gamma and neutron radiation for the medical records developed by ABCC through 10 years, study of survivors. The benefits that could result from this are enormous. Obtaining new data on doses, and through use of the ABCC medical records, their subsequent effects may well provide information that will permit the administration of improved treatment of radiation effects on man. Two of the major laboratories of the AEC are cooperating on this program. They are Oak Ridge National Laboratory and Los Alamos Scientific Laboratory. In addition, the Division of Biology and Medicine of the AEC is being assisted in

this program by the Brookhaven National Laboratory, the Air Force School of Aviation Medicine, the Army Surgeon General's Office, and the Naval Medical Research Institute.

BLAST EFFECTS ON STRUCTURES

Studies of blast effects on shelters and structures are sponsored principally by FCDA. Included are reinforced-concrete home-type shelters for a few persons and so-called mass shelters, capable of holding large numbers of people as well as performing dual functions, such as serving as a parking garage in ordinary times. Also, there are some industry-sponsored items; namely, a protective vault for records, and a windowless reinforced-clay masonry structure. Three reinforced-concrete dome structures are being subjected to overpressures in several ranges to obtain engineering design data for use in future mass shelter designs. Through a United States architect-engineering firm and FCDA, France and West Germany are testing a number of shelters of their design. This represents the first time other nations have included structures or otherwise participated in the Civil Effects Test Group. In addition, a variety of valves, devices, and equipment will be tested for use as shelter components.

BLAST BIOLOGY

The present state of knowledge makes mandatory further studies relating to blast biology. These investigations are being carried out by the Lovelace Foundation and are directed toward obtaining more information on the primary, secondary, and tertiary effects of blast. They are a continuation of the work begun during 1953–55, where together with other valuable data for the first time a means was devised of obtaining usable information on numbers and types of missiles (flying bricks, timber, glass, etc.) per unit area and on the penetrability of glass and masonry fragments and other small missiles likely to be produced in an urban area that has been subjected to a nuclear blast. It is expected that the studies during plumbbob will provide equally valuable information on the problems associated with biomedical effects of static pressures and dynamic pressures sufficiently strong to translate bodies the size and weight of a man from a state of rest to a state of motion.

COUNTERMEASURES AND TRAINING

One of the most important new programs that will be initiated during Plumbbob is work by the Naval Radiological Defense Laboratory on countermeasures against fallout radiation. The proof-testing of radiological shelters and typical buildings is expected to produce data useful in practical applications and guidance for planning a long-range program on methods of survival and continuing occupation of areas that have been subjected to heavy radioactive fallout. This program is designed to provide confirmation and applicability of laboratory theories and methods of decontamination to the large-scale recovery of areas contaminated by radioactivity and in addition to develop data on scaling from low yield to megaton detonations.

Our program includes several training exercises and an offsite radiological defense project of especial importance to civil defense. In addition, other projects will include the field testing of aerial monitoring equipment, and the indoctrination and training of radiological defense personnel drawn generally from State and community civil defense organizations. The field testing of commercially produced radiation detection instrument is included in these projects.

INSTRUMENTATION AND SUPPORTING SERVICES

The instrumentation and supporting services concerned with radiation, blast, thermal, technical photography, are self-explanatory and are designed to give necessary measurements and records to project authors for use in reaching conclusions and in the preparation of technical reports. To supplement and make these physical measurements more meaningful, biological materials, and dosimeters are used to provide data for correlating exposures with effects and extrapolating the findings to probable physical effects on human beings. This requires for Plumbbob several species of animals such as mice, guinea pigs, primates (monkeys), dogs and swine—all of which you will recognize as routinely used in biomedical research.

SUMMARY

It is emphasized that probably the most significant aspect of the Civil Effects Test Program, Operation Plumbbob, is the coordination of continuing laboratory research and less frequent test activities in planning projects to provide information essential to an adequate understanding of nuclear effects on life in all its phases. This coupling provides a continuous flow of basic data usable in immediate practical application and in planning of future research into the means of national self-protection, individual survival, and accommodations of medical practice to the atomic era.

In any case, peace or war, we are already well into the atomic age. Learning to live with the byproducts of nuclear reactions is now necessary and urgent. In addition to the necessity for developing military strength, the weapons testing programs furnish a unique opportunity for providing indispensable information to this end. Additionally, opportunity is provided for the training of key personnel in the theoretical and practical aspects of dealing with environmental radiation in the great variety of situations in which it occurs.

Dr. DUNHAM. He is so busy at the tests. I have also the remarks he made at a press conference at the beginning of Operation Plumbob, which again outlines the civil-effects program.

Representative HOLIFIELD. I think it is very important that the American people know that these tests in Nevada have a much greater effect than just the testing of weapons. There is the testing of materials, the learning of how to protect from radiation, the effect on animals and all of these things which go toward furthering our knowledge of radiations involved in these Nevada tests.

Dr. DUNHAM. That is very true. It not only gives us basic knowledge for all radiation problems, but as long as there is a possible threat of nuclear warfare, it gives us information that is absolutely vital for the defense of the country.

Representative HOLIFIELD. I think the listing of the research projects which you have made in this speech and also the listing of contracts, which are another part of the record, will assure the American people that there is a deep concern and a very wide range of studies in these fields, and that we are not being careless or indifferent regardless of differences of opinion as to what the effects mean. We are at least trying to scientifically get these effects.

Dr. DUNHAM. Yes.

Representative VAN ZANDT. Dr. Dunham, in connection with the use of water for the purpose of attacking the radiation hazard, is that possible? What I have in mind is a pressurized water hose being used to wash off the contamination.

Dr. DUNHAM. That is no question you can hose the fallout material off. Certainly the type of material which came down in the Marshall Islands, which was visible large particles, one could get rid of a great deal by ordinary pressure.

Representative VAN ZANDT. What about the ordinary sprinkler?

Dr. DUNHAM. You have to watch that if you hose it off the roof and sides of the building, and it collects at the edge of the building, you may actually build up more radiation intensity in the building than if you left it alone. One actually has to move it some distance. This becomes quite a problem sometimes.

Representative VAN ZANDT. I understand this practice has been very effective aboard ship.

Dr. DUNHAM. Very effective. I think NRDL has done extensive studies.

Representative HOLIFIELD. I think that distinction between a ship and land is very important because as you say the removal from the walls or roofs of the building means that you are removing it into the soil where people walk.

Mr. DUNHAM. That is right.

Representative HOLIFIELD. Previous testimony from, I believe, Dr. Alexander from the Agriculture Department, was to the effect that it was very difficult to leach this material from the soil.

Dr. DUNHAM. That is correct. It takes years.

As I see it, the areas of greatest immediate need for information are:

1. Better predictability of the properties of nearby strontium 90 fallout: By that I mean whether it is soluble or relatively insoluble, and there is evidence that the near-in fallout is less soluble, and would be less available to plants than the fine particles—better predictability of the properties of nearby strontium 90 fallout, that having tropospheric dissemination, and that getting into the stratosphere for each type of weapon and for each circumstance of burst (ground, low air, high air, etc.). This is very difficult and can only be learned at weapons tests.

2. Amount and distribution of strontium 90 and other fission products in the stratosphere and more precise estimates of holding time in the stratosphere: We will know much more about the first of these in a year's time.

As Dr. Libby indicated, we will know considerable more about that in a year's time as a result of our balloon sampling.

3. Strontium 90 toxicity: In 10 to 15 years we will have experimental data in dogs which will firm up the maximum permissible body burden of strontium 90 for all ages and will have determined whether strontium 90 is ever leukemogenic in dogs and presumably in man, and will have gone a long way to settling whether or not the bone tumor effects of strontium 90 have a threshold.

4. True doubling dose for mutation rate in human germ cells; this will take many years to accomplish, if ever.

5. Tolerable mutation rate for the human race: I use the word "tolerable" advisedly. This again will take many years and will never be exact because of human social patterns.

6. Leukemogenesis and effects on life span by low level external radiation exposures: A study on the latter in several thousand mice at Argonne National Laboratory will be completed in 2 to 3 years. A small scale study in dogs has been going at the University of Rochester for 6 years. This has another 8 to 10 years to go. Related to this is an intensified effort to get more acurate estimates of the true exposures of the Japanese irradiated at Hiroshima and Nagasaki. We attack this from two standpoints. One is to get more exact information about the exact location of the survivors, the type of structures, by aerial photography, and by studies now going on in Nevada attempting to get a much better idea as to what the shielding properties of different materials are, housing materials and the like, to the various types of mixtures of neutrons and gamma rays characteristic of the two weapons detonated in Japan.

I have transmitted separately a more detailed summary statement of the Atomic Energy Commission's biomedical program related to biological hazards of radiation.

(The detailed summary referred to follows:)

U. S. ATOMIC ENERGY COMMISSION, DIVISION OF BIOLOGY AND MEDICINE

Summary—Studies and research projects on fallout problems and related research on the biological hazards of radiation

	Scientific man-years	Amount (in thousands)
1. Sampling and analysis of radioactive fallout, including fission product toxicity and transport:		
(a) Sampling and analysis of radioactive fallout (Sunshine project)	253	[1] $1,193
(b) Research on the biological hazards of radioactive fallout (Sunshine project)		[1] 4,424
2. Effects of radiation on humans, mammals, and other organisms (exclusive of genetic studies)	449	9,168
3. Treatment and methods of ameliorating radiation effects	60	1,338
4. Genetic effects of radiation:		
(a) Studies of human genetics and of genetic effects of radiation on human cells and tissue culture	12	154
(b) Experimental studies of the genetic effects of radiation on species other than man	71	1,314
5. Biochemical and microbiological studies of radiation effects	110	1,472
6. Environmental studies	4	52
7. Dosimetry research: The development of improved methods of measuring radiation	47	1,026
Total	1,006	20,141

[1] A breakdown of these totals appears in the following pages.

In addition to the research programs recapitulated above as concerned with fallout problems and related research on the biological hazards of radiation, the AEC's Division of Biology and Medicine supports a sizable program of research involving the utilization and better understanding of nuclear energies.

This portion of the program involves cancer research and other atoms for peace uses; radioisotopes in medicine; improvement of crops in agriculture; and many other projects less closely related to the fallout problem.

[In thousands of dollars]

Installation	Radiation effects on biological systems (1)	Combating radiation detrimental effects (2)	Beneficial applications (3)	Biomed problems (4)	Dosimetry and instrumentation (5)	Total

Dr. DUNHAM. I call your attention to the first page of that in which it says that there are only four people working on environmental studies. The reason that happened is that in the hurry to get this material to you, we failed to take cognizance of the fact that most of the environmental studies now going on are lumped under the first group, sampling and analysis of radioactive fallout. So that this figure here looks very small, but that does not mean that we are not doing extensive studies in Nevada, and elsewhere, but they are listed in item 9.

I would like to at this point call upon Dr. Shields Warren, with your permission, to say a few words about research in this area.

Representative HOLIFIELD. I was going to ask Dr. Warren and Dr. Brues and Colonel Bach and Dr. Shelton if they wanted to comment on your statement.

Dr. Warren, will you lead off?

Representative COLE. May I interrupt for a moment to express my personal admiration for the appearances Dr. Dunham has made throughout these hearings and particularly this morning. I have been tremendously impressed with his grasp of the problem and his knowledge of the details of it. I congratulate you on it. I think the Commission is very fortunate in having a person of your capacity as Director of the Division of Biology and Medicine. The public is fortunate in having you as a public servant. I compliment you in the highest terms. I am very much impressed, and I am amazed that a person of your talents is willing to sacrifice your life to work for the Government for the pittance that you get.

Dr. DUNHAM. Thank you very much, Mr. Cole.

Representative VAN ZANDT. I have a question of Dr. Dunham. For the benefit of the record, can you describe briefly what happened to the animals that were on the Marianas in the 1954 test? There were 45 or 47 of them, as I recall. Are you familiar with the study on those animals?

Dr. DUNHAM. In the Marianas?

Representative VAN ZANDT. On the Marshalls.

Dr. DUNHAM. You mean the animals on Rongelap. Some of them were recovered almost immediately and taken to the Naval Radiological Defense Laboratory where some were sacrified immediately to find the body burden and some were kept for a period of months to discover the excretion rates and more recently a few more animals were found at the recent survey and similar studies have been done at the Radiological Defense Laboratory.

Representative VAN ZANDT. Is it possible for you to prepare a short statement giving the history of those animals and make it a part of the record?

Dr. DUNHAM. I would be happy to do so.

(The information referred to follows:)

UNITED STATES ATOMIC ENERGY COMMISSION
Washington, D. C., June 28, 1957.

Mr. JAMES T. RAMEY,
Executive Director of the Joint Committee on Atomic Energy,
Congress of the United States, Washington 25, D. C.

DEAR MR. RAMEY: Enclosed is a statement giving the history of the animals on Rongelap which Representative Van Zandt requested us to furnish for the record during the fallout hearings on June 7.

Sincerely yours,

CHARLES L. DUNHAM, M.D.,
Director, Division of Biology and Medicine.

Animals (swine, ducks, chickens) present on Rongelap Island were permitted to continue to live on the island and then were collected at time intervals up to about 2 months after the fallout had occurred. They were then sacrificed serially up to 6 months after the time of detonation. Under these conditions it is estimated that intake of the fallout material may be higher from consuming foods having external contamination than through the soil-plant-animal cycle. It would be expected that the eating habits of animals would result in greater intake of such material than for humans. Yet after living in this environment during the 2 months of heaviest contamination there were no significant gross changes nor pathological changes which could be ascribed definitely to radiation at the time of the examination (sixth month). A summary of the data is contained in the tables 1 and 2 attached, taken from Some Effects of Ionizing Radiation on Human Beings.

Analyses of a rooster and some rats that lived for 2 years in that area before collection and sacrifice, yielded similar negative pathological results. Table 3 summarizes these data. It will be noted from this table that the internal deposition of strontium 90, the isotope of greatest concern, is less than the maximum permissible concentration for adult atomic energy workers (1,000 sunshine units). Yet during this period of time the external radiation dose out-of-doors was at least 400 roentgens. These data definitely indicate that for times immediately following a detonation the external gamma exposure would be the dominant hazard.

A full account of these data may be found in Some Effects of Ionizing Radiation on Human Beings, and the forthcoming publication Radiological Contamination of Certain Areas in the Pacific Ocean From Nuclear Tests. Both of these documents can be obtained from the Superintendent of Documents, United States Government Printing Office, Washington, D. C.

TABLE 1.—*Mortality and external radiation dose of animals from the living areas of Rongelap and Utirik*

Animals	Series A			Series B			Series C			Series D			Total		
	200 roentgens (day 8) [1]			330 roentgens (day 25) [1]			340 roentgens (day 33) [1]			340 roentgens (day 51-53) [1]					
	Total received	Dead	Sacrificed	Total received	Dead	Sacrificed	Total received	Dead	Sacrificed	Total received	Dead	Sacrificed	Total received	Dead	Sacrificed
Hens	6	[2] 1	[2] 1				20	[3] 2	[4] 2	11	[5] 5		37	8	3
Roosters	1						2	[6] 1		1			4	1	
Chicks							9	9					9	9	
Ducks							4		[7] 1				4		1
Pigs	1		[8] 1	7		[9] 4				[10] 3			11		5
Cat	1												1		
Total													66	18	9

[1] Day of collection past detonation and external dose.
[2] 23 days past detonation.
[3] 42 and 43 days past detonation.
[4] 44 days past detonation.
[5] Nos. 96, 39, 35, 7, and 24 were dead 67, 74, 92, 99, and 130 days past detonation respectively.
[6] 49 days past detonation.
[7] 56 days past detonation.
[8] 45 days past detonation.
[9] Sow and Nos. 6, 24, and 25 were dead 33, 57, 82, and 82 days past detonation respectively.
[10] Animals from Utirik; all others from Rongelap (group IV area animals received 22 roentgens external dose).

TABLE 2.—*Radiochemical analysis of tissues and urine of pigs from Rongelap on 82d day postdetonation*

BETA ACTIVITY—D/M/TOTAL SAMPLE

Sample	Gross activity $\times 10^{-3}$	Sr^{90} $\times 10^{-3}$	Ba^{140} $\times 10^{-3}$	Total rare earth $\times 10^{-3}$
Pig #24 (25.8 kgm):				
Skeleton (total)	8,890	5,660	660	1,010
Liver	31	0.40	0.33	6.4
Colon and contents	12	5.0	2.4	3.2
Lung (alveolar)	1.5	0.22	0.20	0.8
Stomach	1.2	0.22	1.1	1.3
Intestine (small)	2.3	0.62	0.50	0.51
Kidney	3.3	0.21	0.42	0.74
Remaining tissues	690			
Total	9,630	5,667	665	1,020
Urine sample, 24 hours	13	8.7	1.2	1.6
Pig #25 (22.7 kgm):				
Skeleton (total)	8,600	5,100	530	690
Liver	27	0.53	0.20	5.5
Colon and contents	16	5.0	3.2	4.9
Lung (alveolar)	1.1	0.26	0.23	0.33
Stomach	2.0	0.29	0.13	0.39
Intestine (small)	2.6	0.83	0.88	0.88
Kidney	3.1	0.14	0.19	0.52
Remaining tissues	220			
Total	8,870	5,107	534	702
Urine sample, 24 hours	6.2	4.4	0.40	0.54

SUMMARY

Gross beta activity	Skeleton	Total body	Urine (24 Hrs)
Sr^{90}	62.0	58.0	69.0
Ba^{140}	6.8	6.5	7.9
Rare earth	9.7	9.0	10.5
	78.5	73.5	87.4

All values corrected for decay.

TABLE 3.—*Analysis of rats and a rooster collected on island of Rongelap*

	Wet weight	d/m Sr-90/ sample	February 1956 [1]	
			Ca/sample (gm)	Sunshine units
Rats: carcass [2]	44.7	642±23	0.533	545±19
Do	62.5	315±62	.315	453±90
Do	82.3	367±21	.353	470±27
Rooster:				
Femur	[3] 26.0	1,210±39	5.19	105±3
Tibia	41.0	5,702±119	9.50	272±5

	Sr-90	July 1956 [4]	
		Calcium	Sunshine units
Rats: Bone	245±5 d/m/g/wet	171±9 mg/g wet	644

[1] Naval Radiological Defense Laboratory.
[2] Does not include head, femurs, tibiae, and viscera.
[3] Dry weight of 2 femur halves.
[4] Applied Fisheries Laboratory, University of Washington.

Senator ANDERSON. I would like to have you see a letter that a Senator from Nevada received, and I will read it aloud. You tell me how you would feel if you were the Senator from Wyoming. I will leave the doctor's name out until I have his permission to insert it in the record. I guarantee it is an authentic signature of a radiologist at Reno, Nev.

The May 28 nuclear tests here in Neveda were of considerable concern to me as a doctor and a radiologist. The fallout as measured on my radiation survey meters was anywhere from 3 to 6 times above the acceptable tolerance level (that is 2 milliroentgens per hour or 50 milliroentgens per day) for the first 48-hour period. The local newspapers quoted reassuring phrases from the AEC to the effect that the above intensity of fallout was negligible and without danger and that the halflife of the radiation sources was calculated to be 12 hours.

This last statement is erroneous. One of the rules which the AEC enforces among users of radioactive isotopes is that residues of such isotopes be kept stored under appropriate protected conditions for 10 half lives, which is a period of decay, at the end of which the radioactive material is considered impotent. Yet, I find that after 10 half-life periods here in Reno there is still a 1.2 milliroentgen per hour radiation present. Actually, if the original information were accurate, at the end of the 10 half-life period it should be hardly detectable by my survey meters. This can mean one of two things: Either the estimated half life was in error or we have been revisited by fallout material dependent upon wind changes.

It is quite true that 50 milliroentgens per day (or 2 milliroentgens per hour) is considered to be of tolerance level. However, we must consider that all radiation received by this population is on an accumulative basis; and if we are to be periodically exposed to this much radiation, the accumulation can mount up to levels, which in the light of our present medical knowledge, becomes quite significant and hazardous. Actually, no one knows at exactly what dose level significant genetic changes and malignant tumors may suddenly appear in the human. So, it behooves us to practice utmost caution at all times in this regard.

Politics, physics, and medicine seem to be primarily concerned with nuclear tests and observation. But, from where I sit, only the medical man seems most keenly concerned with the future possibilities of these radiation dangers. So, I wish to add my protest to the situation which exists here in Nevada. I want more assurance that there is justification for continued testing, and I wonder if testing grounds could not be removed to more remote, uninhabited areas of the world.

I am not going to worry about your comments on the latter two questions, but what about these 10 half lives and what his testing devices show?

Dr. DUNHAM. I don't know what testing devices he has used. Dr. Dunning, a biophysicist in my division, who spends a good deal of time at the tests working closely with the radiation safety group and the Public Health Service there, has handed me a note to the effect that a dose of 50 to 100 millirep is now estimated for anybody who would continue to live in Reno for the rest of his life.

Senator ANDERSON. That is the estimate. What does that do to you?

Dr. DUNHAM. I think there has been a great deal of testimony during the past 2 weeks on the problem of whether there is a threshold at very low dose rates. This certainly is a low dose.

Senator ANDERSON. Geneticists all seem fairly well agreed that there was no threshold.

Dr. DUNHAM. That is correct. I don't think there has been any question of the geneticists' concept that the genetic effects are all cumulative, and at any level, high or low.

Senator ANDERSON. Would the Senator who got this letter be justified in answering the doctor and say you just have to grin and bear it?

Dr. DUNHAM. I would like to put this somewhat into perspective. If this doctor were to fluoroscope a patient suspected of having an ulcer of the stomach or a cancer of the bowel, the dose to the gonads—here we are talking about genetic effects—would be somewhere in the vicinity of 20 to 30 or possibly more roentgens, not 50 to 100 milliroentgens.

(NOTE.—These figures, 20 to 30 roentgens, may be high. Pullman and Laughlin, in their preliminary edition of Section III: Gonadal Dose Produced by the Medical Use of X-rays of the Report of the Genetics Committee of the National Academy of Sciences Study of the Biological Effects of Atomic Radiation, give an estimate of the gonadal dose from a study of the colon as from 4 to 15. The gonadal dose from a study limited to the stomach only would be less than 1 roentgen. This presupposes modern X-ray and fluoroscopy equipment and the taking of adequate precautions.)

Senator ANDERSON. As Dr. Selove pointed out in that instance the doctor would weigh the possibilities for good along with the possibilities for damage. In this particular instance there is no possibility for good. As far as the individual is concerned, he just gets damaged.

Dr. DUNHAM. That is correct to the extent that he would be damaged. I think that is one of the purposes of these hearings, that is, to point out and give the committee information on what factors have to be weighed when we talk about testing nuclear devices. Is it worth it to the country as a whole.

Representative HOLIFIELD. That milliroentgen is a thousandth of a roentgen?

Dr. DUNHAM. Yes.

Representative HOLIFIELD. How would you express a millionth?

Dr. DUNHAM. A millionth would be a millimilliroentgen.

Representative HOLIFIELD. You do not get that low in measuring.

Dr. DUNHAM. I don't think one can measure it satisfactorily that low that way and one has to begin to talk about counts per minute.

Representative HOLIFIELD. Thousandths is about the lowest?

Dr. DUNHAM. That is correct. Certainly film badges don't get that low.

Representative COLE. If you did get that low, what name would you give it?

Dr. DUNHAM. A microrentgen.

Representative HOLIFIELD. That is the same as a microcurie?

Dr. WARREN. Yes.

Representative HOLIFIELD. Dr. Warren.

STATEMENT OF DR. SHIELDS WARREN, NEW ENGLAND DEACONESS HOSPITAL, BOSTON, MASS.

Dr. WARREN. Thank you very much, Mr. Chairman.

Representative HOLIFIELD. Dr. Brues, would you like to come forward, and Lieutenant Colonel Bach and Dr. Shelton, if you wish to have anything to say, will you please come forward? Is Dr. Schulert here?

Dr. SCHULERT. Yes, sir.

Representative HOLIFIELD. Dr. Crow's name is here, too. I do not know whether he is still with us or not. I understand that Dr. Shannon and Dr. Burney have separate statements, so we will not ask them to come forward at this time.

You may proceed, Dr. Warren.

Dr. Warren. Thank you. I appreciate the kindness of the committee in permitting me to make a statement relative to the present research program of the Atomic Energy Commission in this field of radiation, and to make comments as to the program and its possible future trends.

First, I would like to restrict myself to the fields of biology and medicine, as I am not competent to venture beyond them. I have some hesitancy in making recommendations as a medical man even in the field of biology. However, I would like to say that the program of the Division of Biology and Medicine of the AEC, which you have just heard outlined so clearly by Dr. Dunham, has within the limits of budgetary approval and personnel, attained as much in the way of research results as could be expected from any program.

Initially in this program there was a very real limiting factor, the scarcity of competent scientists. Scientists are still scarce, but are being trained rapidly. One of the best ways to attract scientists is to have adequate opportunities for them to work in any field. As I said, Dr. Dunham has outlined for you the present program with regard to radioactive fallout and certain suggested additions to it. I heartily second his suggestions, but would go somewhat further since he has restricted his comments largely to the factors that are immediately referrable to radioactive fallout.

Much of our knowledge with regard to the effects of radioactive fallout must be obtained by advancing our knowledge of other types of radiation, since fallout occurs in such very small quantities as to produce recognizable changes only with the greatest rarity. Therefore, there must be much research done in the general field of pathological effects of radiation on the one hand, and the effects of radiation on heredity on the other.

To be more specific, I would recommend expansion of research on the effects of radiation on the cell, both in its resting and its dividing state, and expansion of the study of the effects of radiation on enzyme structure. Additional studies are desirable on the effect on both acute and chronic radiation on animals, both as to specific changes and as to more subtle changes, such as shortening of the life span.

Studies of human population genetics, a relatively new science, should be greatly expanded, and the present studies in mammalian genetics should be multiplied several times. These studies, together with those recommended by Dr. Dunham and others, should not be at the expense of the present research program of the Division of Biology and Medicine of AEC since those existing studies, I believe, are well chosen and significant. Rather, the research budget of the Division should be materially increased. I think this should be done in an orderly fashion. A sudden increase is not a practical thing to undertake.

I would like to emphasize in regard to all of the research done in the universities—indeed practically all research in biology and medicine in this field—that there has been no restriction, no withholding of data. All of us working in this field have been free to publish our results exactly as they have occurred. There is absolutely no effort on the part of AEC to withhold significant information.

I think it might be worthwhile to comment briefly on the very careful studies on the fallout problem that are made both in this country and abroad. As you have heard, the groups that are following this

field of work are several. In this country, of course, the Atomic Energy Commission is the first and most active. The Department of Defense plays a large role. The Federal Civil Defense Administration is keenly interested. The Public Health Service is carrying on a number of very valuable studies. These agents all cooperate with one another and with the Weather Bureau, the Department of Agriculture, and other governmental groups, as you have heard, that have special interests in the field.

I think it is pertinent also that there are in this country several unofficial but nonetheless very well constituted groups that are following this problem of fallout and research reated to it. The most expert are (1) the National Committee on Radiation Protection which in turn is affiliated with the International Committee on Radiation Protection, and the International Committee on Radiation Units. You heard from Dr. Taylor, its chairman, as to the way its work is carried on and what it does.

(2) The Committee on Radiation Effects of the National Academy of Sciences, which, as you know, has made valuable reports and are continuing to follow the problem.

Representative COLE. Mr. Chairman, I wonder if it might not be appropriate—I intended to ask Dr. Warren about it later—at this time to indicate the distinction between the United Nations Scientific Committee on Radiation, the International Committee on Radiation Protection, and the International Committee on Radiological Units There is coming to be an abundance of international committees in the field of radiology, and I would like you to explain the origin, the genesis of each· how they overlap and so forth.

Dr. WARREN. Yes. In the mid-1920's the people working in the field of radiology and radiobiology became concerned over the problems of radiation protection and the fact that many of the people who were going into radiology were being damaged by the radiation they received, and were not being taught how to protect themselves.

Consequently, in several countries National Committees on Radiation Protection were established, first informally. Those in this country were made up of representatives of scientific societies which cooperated with the National Bureau of Standards and at present the activities of the National Committee on Radiation Protection are housed at and aided by the personnel of the National Bureau of Standards.

The chairman of these various national committees joined informally in an international group. This international group first met every 3 years at the International Congress of Radiology. As the problems became more multiple they have met more frequently.

Representative COLE. You say it began in 1920?

Dr. WARREN. That began, I think, in formal fashion in either the late 1920's or the early 1930's. Its last meeting was the end of April in Switzerland. Dr. Taylor, from whom you heard, together with Dr. Wycoff of the Bureau of Standards, were the United States representatives there.

This is a purely informal group which has had such efficiency in its work, such scientific standing, that the AEC and practically all of the governmental and State agencies accept its ruling as official, and through the recording of these in the Federal Register they have the force of law.

These committees are entirely apart from the United Nations committee. If I could reserve comment on that for just a few minutes while I speak of some of the other agencies, I would like to come to that in more detail later.

Among other competent groups working in this country are many research groups in universities, in research laboratories throughout the country; the Federation of Atomic Scientists, who had a representative here, is also keenly interested. Then there are a number of other groups that have committees having to do with atomic energy, and concerned with problems of protection. Even the United States Chamber of Commerce and the AFL-CIO are interested in this field.

Abroad there is much emphasis on the problems of fallout and the official report of the British Medical Research Council contains much useful data which, as you have heard, correlates closely with those of our own National Academy of Sciences.

The World Health Organization has also considered certain aspects of the radiation problem.

At the instance of the United States, the General Assembly of the United Nations has appointed a scientific committee to study radiation problems. This committee consists of representatives of 15 nations. I am the representative for the United States. Dr. Brues, sitting beside me, is one of my alternates and has been extremely helpful. This committee has been studying the problem of fallout and related aspects of radioactivity most intensively, and its report will be presented to the General Assembly in June of 1956.

Representative COLE. May I inquire, Dr. Warren, if the meeting of this committee last fall in New York was the first of its meetings?

Dr. WARREN. No, that was the second of its meetings, Mr. Cole. There was one in Switzerland in April. The next, I believe, is scheduled for New York in January. However, there is a great deal of work done besides that being done at these various meetings. There is a secretariat which is continuing to digest all of the information that has been turned in. All of us receive information from all over the world. At the present time, I am reading through a stack of reports, from virtually every country in the world, that is close to 3 feet high. I have gotten two-thirds of the way through it now. Various members of this United Nations Committee have been given the responsibility with the secretariat of preparing separate chapters of this report which will probabily be about a 200-page report when it gets done.

Representative COLE. How long has the committee been in existence? Has it been about a year?

Dr. WARREN. As I remember it, it came into existence about a year and a half ago. Do you remember, Dr. Brues?

Dr. BRUES. November before last, I believe.

Dr. WARREN. Yes. It will make its report, as I say, for June 1958.

CHAIRMAN DURHAM. Why is it just 15 nations, Doctor?

Dr. WARREN. It was felt that a group of that size would be a group that would represent a high degree of scientific competence from the different countries. It would have available to it information from all over the world and all of the member nations of the United Nations and its allied organizations. It would be a small enough group to

work effectively. If it had been a group representing every one of the members of the United Nations——

Chairman DURHAM. Can you give us the names of the 15 countries?

Dr. WARREN. I believe I can. Australia, Argentina, Belgium, Brazil, Czechoslovakia, Egypt, France, India, Japan, Mexico, Sweden, U. S. S. R., United Kingdom, United States, and Canada.

Chairman DURHAM. Russia is a member of the group?

Dr. WARREN. Both Russia and Czechoslovakia are members of the group.

Representative HOLIFIELD. How many meetings has this committee had?

Dr. WARREN. This has had three formal meetings. The reason I was hesitant is that we have had so many informal meetings that it is very difficult to keep track of them. You might say that those of us working in the group are almost in continual session through contact with the secretariat by mail and so on.

Representative HOLIFIELD. Do you have an adequate secretariat to collate the material that is sent in and is there a wide collation and distribution?

Dr. WARREN. Yes, there is a very wide collation and distribution. The great bulk of the material has come from the United States, because we have accomplished more research than any other of the nations.

Chairman DURHAM. How do you report, Doctor? Do you report directly to the American representative?

Dr. WARREN. As the representative for the United States, I report to Mr. Lodge as the Ambassador to the United Nations. However, our committee as a whole is a creature of the General Assembly and reports to the General Assembly.

Chairman DURHAM. It reports directly to the General Assembly?

Senator ANDERSON. How does this information get to the people of this country?

Dr. WARREN. It is the responsibility of the various representatives to bring all pertinent information which is made available to them—this is all circulated—to the people of their country. The final report of the committee will be an open report to the General Assembly and through them to all the member nations and distributed throughout the world.

Senator ANDERSON. Can you give us the name of the fallout expert in Argentina?

Dr. WARREN. The head of the delegation is Captain Nuñez.

Senator ANDERSON. Is he a radiologist?

Dr. WARREN. He has a background in radiology and radiobiology. I might say that the different countries have chosen people with specific competences which vary with the countries. But each delegation from each country brings all the available information from that country. It is not restricted to the specific competence of the members of the delegation.

Senator ANDERSON. What sort of individual represents Egypt, for example?

Dr. WARREN. In Australia a physicist is the representative. In Belgium a medical man interested in radiobiology is a representative. In Canada a medical man who is a public health official represents the country. In Brazil, a distinguished biophysicist. In Czecho-

slovakia, also a biophysicist. I could go through the list. It is a very varied group.

Senator ANDERSON. This individual from Canada, has he been making any special studies of fallout?

Dr. WARREN. Yes.

Senator ANDERSON. Is that his field?

Dr. WARREN. He is relatively new to this field, but he was chosen by the Canadian Government because they felt him to be thoroughly competent in it.

Senator ANDERSON. Has he been doing work and making studies in fallout? Is that his specialty?

Dr. WARREN. I would say he is essentially an all around public health man who is especially interested in this field and is provided by his Government and the scientists in his country with a great deal of information in this field.

Representative COLE. You spoke of the report of this committee as being a final report. Does that mean that when the report is submitted in June of next year, that the committee will disband and discontinue its work?

Dr. WARREN. We have been appointed by the General Assembly to review the problem, to gather, collate and evaluate information, and to make a report. Our future is entirely in the hands of the General Assembly. I rather assume that they will ask us or successors to us to continue this work. I cannot speak for the General Assembly in any way, of course.

Representative HOLIFIELD. You may proceed.

Dr. WARREN. I would like to leave very briefly the discussion of research and make one further comment. That is this: The ultimate decisions with regard to weapons testing and with regard to the whole development of atomic energy will have to be made, as they have been made in the past, by you and other duly constituted representatives of our people. I believe that the advances in science within the next few years provided research is adequately supported and facilitated will permit obtaining much more conclusive data than now exist as to the feasibility of continued weapons testing. The concern of the world is for disarmament and the elimination of war, of course. I firmly believe as a physician that it is inexcusable for us to jeopardize our own safety and that of the rest of the free world in order to eliminate a risk of as low an order of magnitude as is constituted by any reasonable program of atomic weapons testing.

Senator ANDERSON. Do you think that the proposal made by Dr. Langham which was an overall control of the total tonnage of any fission products going into the atmosphere would jeopardize our production of weapons.

Dr. WARREN. I am not at all an expert in this field, Mr. Anderson. I would not have any opinion. I would hope that it might be feasible to work out some program of this type.

Senator ANDERSON. Would you read again the last paragraph.

> I firmly believe as a physician that it is inexcusable for us to jeojardize our own safety and that of the rest of the free world in order to eliminate a risk of as low an order of magniture as is constituted by any reasonable program of atomic weapons testing.

You there set yourself up as an expert in the field. I am not trying to say it is improper. You testified what you would do.

Dr. WARREN. Yes.

Senator ANDERSON. Having established that, do you thing Dr. Langham's proposal that an amount of 10 megatons of fission production going into the atmosphere each year which we are now doing is about the safe limit?

Dr. WARREN. I feel we would be safe in having that much. I would hesitate to say that is an absolute upper limit. I would think that is a reasonable amount. I would not be worried by a program at that level.

Senator ANDERSON. If you have not made studies in the field yourself, you recognize that the Los Alamos and the Livermore Laboratories have.

Dr. WARREN. Yes. They are most competent.

Senator ANDERSON. If they feel that is a top limit, does that suggest to you that is something we might look to as a proper guide or not?

Dr. WARREN. I would think that this might be very sound indeed. From my own knowledge from the medical standpoint, as I said, I would not be at all worried by a program at this level.

Senator ANDERSON. Almost every time when somebody comments, they talk about limitation on testing as if it meant the elimination of all progress and all testing of every kind. It is like saying to man he should be careful in the amount of protein he takes into his system. But a doctor will say if you do not take any protein at all, many things will happen to you. Somehow we do not get much comment on the suggestion of limitation. It is always that we will abolish it all. This was not the proposal of Los Alamos and certainly has not been my own.

Senator JACKSON. Dr. Warren, what this really boils down to is that we have two risks. One is the risk to the free world if we are not prepared to deal with an enemy that might well bring total atomic hydrogen catastrophe to all free nations. On the other hand, continued testing do present a danger of an undetermined nature to people. We do not have enough scientific data for scientists to speak scientifically, whether they are doctors or pure scientists. There are these two threats. Maybe between the two some kind of reasonable balance can be achieved. Don't you think that is a reasonable approach?

Dr. WARREN. Yes. I think that is a very reasonable approach. That is what I had in mind when I spoke of any reasonable program of atomic weapons testing.

Senator JACKSON. What was your last statement?

Dr. WARREN. I simply said that was the general idea I had in mind when I said "any reasonable program of atomic weapons testing."

Represenative HOLIFIELD. If there are no questions, I will ask Dr. Brues to proceed.

Chairman DURHAM. Before you proceed, Dr. Warren, on the second page of your statement I believe your statement concurs with the statement Dr. Libby made on yesterday in his recommendation of increasing the research program of the Division of Biology and Medicine.

Dr. WARREN. Yes, sir.

Chairman DURHAM. You say "not at the expense of the present research program," but still you recommend an increase in it. Could

you put that on a percentage basis as to exactly what you mean by that type of statement?

Dr. WARREN. What I would think is this, sir. One is that there are a number of other very important problems that are being worked on by the Division of Biology and Medicine than those having to do with fallout. We should not interfere with those. There should be an expansion of the program which I think could perhaps be on the order of—it is hard to say—of an expansion that went up, say, 50 percent in 3 years. Maybe that much again in another 3 years would be 1 that could be handled in very orderly fashion. It would not be wasteful. There would be adequate scientific personnel to see it through.

Chairman DURHAM. In some sections of the whole program, you would place more emphasis on this?

Dr. WARREN. Yes. I think, for example, that we must not lose emphasis on the portions of the program that have to do with how to cure atomic innjuries once they have occurred. We must not lose emphasis on the good things that can be done in the field of medicine and biology with atomic energy. I think it is important that in the development of this whole atomic-energy field that the developments in biology and medicine be advanced on a broad foundation. As an illustration, for example, we began our studies on radioactive strontium long ago before we knew how important radioactive strontium could be. I am sure there are other things in the program that do not look very important at the present time that we will be very glad in 1965 we had started earlier.

Chairman DURHAM. You mean that many new things are showing up on a daily or monthly basis that funnel off some of your research in that direction.

Dr. WARREN. That is right.

Chairman DURHAM. You do feel that the impetus should be on an increased expansion.

Dr. WARREN. I feel this very strongly, sir.

Representative HOLIFIELD. Dr. Brues, did you have any comment to make on the testimony which has been given?

STATEMENT OF DR. AUSTIN BRUES, ARGONNE NATIONAL LABORATORY

Dr. BRUES. Mr. Chairman, I have not prepared a statement, but there might be 2 or 3 things I might say, particularly with reference to the programs as they are carried out at the national laboratories which constitute a considerable portion of the work.

As Dr. Dunham mentioned, the national laboratories are run by contract with various agencies. Ours is operated by the University of Chicago. Yet they are large enough to operate essentially as independent institutions, and they are financed by the Atomic Energy Commission. The fact that there are several national laboratories was established in the original Atomic Energy Act, and in a sense grew out of the fact that there had been several sites at which research was carried out before the Commission came into being. I have felt personally that the diversification of the large research centers into several rather than bringing them together has been a good thing from a number of standpoints. I would say particularly be-

cause it allows a certain flexibility. There is no embarrassment, for instance, if an investigator in one laboratory holds a different view from an investigator in another laboratory; just as in the universities they get together and these things are reconciled by further work.

The programs are defined very much by the individuals who carry out the programs. The amount of masterminding, I think, has been kept at a reasonable and proper minimum. What people in the laboratories are mostly interested in is knowledge of what are the fields which are not being adequately tackled, and what, therefore, may be needed in the way of both basic and practical research. In that sense, of course, it is very useful to keep in contact with one another and with the authorities in the Commission.

The selection of personnel is done entirely at the level of the laboratories themselves, with only the restriction, which actually occurs very rarely, that is placed upon us by the security provisions of the act.

Chairman DURHAM. I agree with you, Doctor. I think the program has been well planned on the basis of the distribution in the universities of the entire country. I think if we built one huge laboratory we would not be as far along as we are today.

Dr. BRUES. The type of work is divided in our national laboratories and I think in most of them, and rather equally, between work which is straight programatic investigation kind of work where we are collecting numbers of figures, work which has more or less immediate practical objective, such as looking for treatments of radiation illness and so forth, and work which some people might consider useless, but as Dr. Warren mentioned turns out very often to be quite useful.

We have on occasion been asked if we could not perhaps think it would be important to gain some information in a certain area. Often, actually this information has been at that time fairly well gained by investigators who perhaps through an intuitive process or their curiosity have been working on it. This certainly was true of strontium. We have dogs in the laboratory which received some of the earliest radio strontium 10 years ago. This is not part of the program that would have been given us at the time, but obviously animals of this sort are very important, at least in determining the specifications for other experiments which may be started at this time.

Senator ANDERSON. When Dr. Dunham presented his paper, he said on strontium toxicity:

> In 10 to 15 years we will have experimental data in dogs which will firm up the maximum permissible body burden of strontium 90 for all ages, and will have determined whether strontium 90 is ever leukemogenic in dogs and presumably man, and will have gone a long way to settling whether or not the bone-tumor effects of strontium 90 have a threshold.

Are we to understand that to mean that in 15 years or so we will find out whether it is dangerous to let strontium 90 to be lying around, and if so, who much of it we can have?

Dr. BRUES. I think we are sharpening our knowledge on that all the time. I think it will take another generation of long-lived animals probably before we have the sharpest figure that we can reasonably ever expect to get.

Senator ANDERSON. But by that time if we can believe the upward sweep of testing, with other countries getting into the act, and everybody coming along with their own weapon testing, we could possibly

have done heavy damage to ourselves, could we not? Is there any way of speeding this up? We build a bomb by a process of speeding up. We have had estimates of how long it would take to develop a bomb.

Dr. BRUES. I think, sir, that the way in which this may be and probably will be speeded up is by the expansion not only of these predictable programs, but of the type of work which is going on in what I term the useless areas. In other words, investigation of how cancer is produced by radiation, and indeed how cancer is produced by other agents in comparison with this. I think that we may therefore arrive at basic knowledge in this way which will resolve some of the questions that we are also asking in case that should not pay off in the area of carrying out practical experiments.

I might say these animals which we treated 10 years ago, which have never shown signs of damage, received about 700,000 sunshine units of strontium. The only trouble with this is that there were only three of these dogs. As you have heard, you have to have large statistical numbers in order to sharpen things up.

Senator Anderson. Do you think it will be 10 to 15 years before we know whether testing at the present levels were continued would present any perils to people from strontium 90? I am confining it strictly to strontium 90.

Dr. BRUES. To answer that I would have to go into some questions that were discussed yesterday.

Senator ANDERSON. I do not mean to prolong this.

Dr. BRUES. I believe that it is very likely that we will get at some very fundamental truths about cancer sooner than that period which will tell us this, but we must at the same time be carrying on experiments which will give us the figures, so to speak.

Senator ANDERSON. I say that because the third paragraph of Dr. Dunham's paper says that it will be 10 or 15 years before we get sufficient data, and the fourth paragraph said that the true doubling dose for the mutation rate would take 8 years, if ever, and everything suggests an awfully long time. A tolerable mutation rate would take many years and never be exact. It is a very discouraging picture. The probabilities are that we will never know anything about anything. Is that your feeling?

Dr. BRUES. I would feel that perhaps I am entitled to be more optimistic than Dr. Dunham, because it would not be so easy to come back at me and chastise me for making a prediction that was not sufficiently conservative. I am more optimistic than is indicated there.

Senator ANDERSON. I was not trying to pick a quarrel with Dr. Dunham on this. I was hoping there would be a little more optimism than this "if ever, and we will never be exact."

Representative HOLIFIELD. We are looking for more sunshine.

Senator JACKSON. I was going to comment, is there such a thing as an exact science?

Senator ANDERSON. We hope we get some answers that we regard as pretty specific.

Representative HOLIFIELD. Would there be any other comments? Did you have something else, Dr. Brues?

Dr. BRUES. I would like to say one other thing very briefly, sir, and that is to underline Dr. Warren's remark that there has not been any

interference in my experience or the experience of anyone I know with the dissemination of results, no matter what they showed. I have actually some documentation on that. There was a statement made by one of the witnesses the other day that indicated that the principle of life shortening had been kept under cover for some reason not known to the speaker. I will, if you wish, produce some documentation that this was not only not kept under cover, but that these things were given to the public in a publication which came out of the first national radiobiological meeting which was attended by many of those that were present here, and in fact made the scientific public aware of all of the work which had been done in the field of life shortening, raised the questions of cell mutations, and many other things of that sort.

Representative HOLIFIELD. You will concede, however, that speeches before limited number of scientists does not take the place of information prepared which is readily understood by the public and widely disseminated. I am blaming no one for this, but there is a difference in the expression of opinion to a limited group of scientists and actually getting the story to the people.

Dr. BRUES. That is true, of course. That is the general problem which we also have, that of disseminating the knowledge. I think that this meeting served the important purpose of getting many people working in this field. It was quite speculative at the time, but it has resulted in a wide interest. For example, the brilliant work Dr. Hardin Jones told you about the other day was assisted by the fact that this subject was discussed at that meeting which was aided by the Commission.

Representative HOLIFIELD. At this time the Chair is going to interrupt the proceedings. There is a rollcall which the House members have to attend. We will proceed at 2 o'clock this afternoon in this room as we have some important statements which have to be made. We will resume with this part as soon as we return.

Senator ANDERSON. May I ask one question of Dr. Warren. I started out on strontium 90 a minute ago. When you were head of the AEC's Division of Biology and Medicine, was there a proposal put up to you for a study of the chronic effects of strontium 90, and was there some decision taken on it on the basis that it would be a ten-year and very costly study? Do you recall?

Dr. WARREN. My memory is—and it is a little vague—that there was a proposal made of a 10-year study using dogs that would have cost about $5 million a year, as I remember. It is something of that sort. I believe that strontium 90 was included along with radium, mesothorium, and other substances.

(A letter clarifying Dr. Warren's testimony follows:)

CANCER RESEARCH INSTITUTE,
NEW ENGLAND DEACONESS HOSPITAL,
Boston, Mass., August 6, 1957.

Mr. HAL HOLLISTER,
Joint Committee on Atomic Energy,
Capitol Building, United States Senate Post Office,
Washington 25, D. C.

DEAR MR. HOLLISTER: On July 5, 1957, as I was leaving on vacation, I sent a suggested addition to my testimony on the final day of the hearings. In reading this over I am not sure that it entirely answers the question raised by Senator Anderson. If it is not too late to make a change in the proof, the following might be a better way of expressing it.

"Another project that might be thought of in this connection was one made by the Los Alamos Laboratory, as I recall it, but the proposal for which was never formalized. This project had to do with the effects of the inhalation of particulate radioactive substances by dogs. After a good deal of preliminary study it was felt that certain phases of the proposal were very useful and significant. Since suitable inhalation chambers were already available at the atomic energy project at the University of Rochester and only additional animal quarters were required, this experiment was undertaken at the University of Rochester on the completion of the necessary changes in animal quarters."

Sincerely yours,

SHIELDS WARREN.

Senator ANDERSON. Did you not recommend pretty firmly against it?

Dr. WARREN. I recommended against that particular study but I recommended in favor of continuing studies in this field and got together a group of all the competent and interested people to establish at the University of Utah a study on dogs which started, as I remember it—I will have to ask Dr. Dunham as to the year—was approved and started in 1950, Dr. Dunham tells me. There had to be some construction which slowed it down for some months. That study is the one to which reference has been made now, and useful data are coming from this.

I think that one has to keep in mind this point, Mr. Anderson. One always has to weigh the types of research undertaken in relation to the funds and personnel available for that research at the time. When this research was proposed in its original form, it seemed impractical and too costly for the data that hopefully would be obtained. It looked as though this University of Utah study would be a sounder way of approaching the problem, and one within our means, both of available scientists and available funds. I still hold that opinion.

Senator ANDERSON. I do not question you on the available scientists at all, but I do believe that on funds for items of this nature since I have been a member of the Joint Committee, I have had to go to the Appropriations Committee many times and urge them to be somewhat liberal with the Atomic Energy, and I have always found them so, and I only hope that we do get some sort of expanded program in research that may give us a little quicker answers on some of these questions that are very disturbing to a great many people.

Dr. WARREN. I strongly agree with you, Mr. Anderson.

Senator ANDERSON. We will meet at 2 o'clock.

(Thereupon, at 12:15 p. m., a recess was taken until 2 p. m., the same day.)

AFTERNOON SESSION

Representative HOLIFIELD. The committee will be in order. I want to announce that the Chair will have to leave the room at 5 minutes to 3, and, for fear that I may not get back before the witnesses are concluded, I would like at this time, on behalf of the committee, to thank all the witnesses who have appeared during this group of hearings.

The purpose of the committee, as stated in my opening statement, has been adhered to. It was in a limited field. There are other fields

that are of interest to the committee, and undoubtedly the committee will want to go into some of those fields laer. There has also been a great deal of information filed, either in oral form or in written form, with the committee which the members have not had a chance to thoroughly study, nor has the staff had a chance to analyze. So it has been thought best by the subcommittee that we adjourn our meetings today for the purpose of studying these documents and receiving information which has been requested and has not yet been given to the committee. The committee will make a later determination as to whether there will be additional hearings to fill any gaps that we may find in our testimony on this particular specific subject, and also make the determination of going further into fields which are indirectly related to the subject of weapon fallout in the field of radiation. I speak of the fields of industrial hazards, which will encompass large-size reactors, and also the fields of weapon detection, which has a great deal to do with our ability to know when these explosions occur, and, also, our ability to evaluate accurately the amount of fission products which are thrown into the air. Of course, this has tremendous importance in evaluating the overall burden of radiation which would be finally deposited on the earth and its people.

We also have not had time to analyze the weapons effects handbook which is now in print by the military liaison group of the Defense Department and the Atomic Energy Commission, and we may want to go into some of the matters contained in there.

Another very important area in which the committee is interested—which may, in view of certain industrial developments, have to be considered—is the problem of waste disposal from reactors, the methods that are now used to dispose of this waste material, and the safeguards that are in existence at this time and plans for the future in order to protect the people from radiation from waste materials.

We will want to know the quantities, in tons or gallons, of this material which are now in existence, and which are being produced every day and every year, and we will want to have an estimate of the problem that will be involved in the disposal of waste when we have a hundred of these large-size reactors of 100,000 to 200,000, or 300,000 electrical kilowatts of capacity.

We will want to know how the nations abroad are disposing of this waste; whether they are placing them in the ocean, where the contamination might become global; and where the United States is disposing and the methods it uses.

So there are fields which have not been covered, but they are fields which the comittee will get to in the future, no doubt.

The committee reserves the right, of course, to accept and incorporate in the record additional scientific material which has been requested by the members or referred to by witnesses. We also, of course, reserve the right, as I mentioned at the beginning of our hearings, to include answers to specific letters of inquiry to scientists and witnesses which have been sent out and will be sent out for the purpose of clarifying or completing certain areas of inquiry.

Representative COLE. Mr. Chairman, before you do that, since you have indicated that in all likelihood you will not be here at the con-

clusion of the hearings this afternoon, I feel I should now express what I otherwise would have withheld until that time, and that is to join you in the compliment to the witnesses who appeared, and, more particularly, to pay a compliment to yourself for the fine manner in which these hearings have been conducted and the tenor that has attached to the hearings, for which much credit is due yourself. I compliment you and Mr. Hollister, as well, who has prepared this agenda, for the total accomplishments of these hearings which, I am confident, in the course of time will prove to be most valuable.

Representative HOLIFIELD. I thank the gentleman from New York very much.

Representative VAN ZANDT. Mr. Chairman, I would like to join my colleague from New York in that statement.

Representative HOLIFIELD. I am sure, without the help of every member of the committee and the hard work of the staff night and day, both before and during the hearings, we could not have had as successful a conclusion as I think we are going to have in these hearings.

Senator JACKSON. Mr. Chairman, I, too, would like to associate myself with the remarks that have been made with reference to these hearings. I think the chairman and Mr. Hollister and the staff have done a fine job.

I believe that these hearings cannot help but have a favorable impact in the long run on the American people and world opinion. I think the most important thing of all is that we have had the opportunity of having different points of view. Certainly, in large part, the views that have been expressed have been honest scientific opinion, even though the scientists and experts in the field have not always agreed.

Representative HOLIFIELD. Thank you very much. It would be remiss on my part if I did not thank all the witnesses who have appeared before us, and especially do I wish to thank the witnesses from the AEC, and from projects which are under the auspices of the AEC, for their cooperation in preparing their statements and presenting them to us in the complete way in which they have.

Dr. DUNHAM. Mr. Chairman, is it in order that I make a statement on behalf of the AEC, which has appeared before you in several forms, to thank you for the extremely courteous and interested attitude of the committee. I want to assure you that any further information you may require we will endeavor to provide for you.

Representative HOLIFIELD. Thank you very much.

By mutual agreement we are going to reverse the order of the witnesses who have prepared statements, and we will ask Dr. Waterman, Dr. Alexander, Dr. Bach, and Dr. Shelton, and any other scientists who may be present and wish to join, to comment on their statements at their conclusion. I think it may be an orderly way to take the three statements which we have, which I understand are not too long, and have them in order, and then have the roundtable discussion.

At this time we would like to have Dr. Schulert of Lamont Laboratory to be our first witness.

STATEMENT OF DR. ARTHUR R. SCHULERT, LAMONT GEOLOGICAL OBSERVATORY, COLUMBIA UNIVERSITY [1]

Dr. SCHULERT. I have a statement which I prepared for the record. However, I do not believe it is necessary to read the statement in its entirety, since it would involve the repetition of many things that have transpired this morning. The statement involves my personal opinion as to what we should do along the research line in view of the present state of affairs. This, as you know, was quite comprehensively reviewed by Dr. Dunham of the AEC this morning.

I would like to just mention a few of the highlights of this statement.

(The statement referred to follows:)

REMARKS PREPARED FOR PRESENTATION BEFORE THE JOINT COMMITTEE ON ATOMIC ENERGY, UNDER SECTION XII—THE IMPACT OF THE PRESENT STATE OF AFFAIRS: WHAT SHOULD THE RESEARCH PROGRAM IN THE PHYSICAL, GEOLOGICAL, BIOLOGICAL, AND MEDICAL SCIENCES BE?

Arthur R. Schulert, Ph. D., Research Associate, Lamont Geological Observatory, Columbia University, Palisades, N. Y.

This presentation is given as a personal opinion of what the future research program should be in view of the present state of affairs with regard to fallout as discussed at these hearings.

The various testimony which has been presented to date, in spite of conflict in detail, has agreed on 2 basic points: (1) Present fallout represents a definite hazard in that it produces deleterious effects in man and (2) these effects are very small compared to the effect of background radiation which has always been with us. As has been brought out in previous testimony the problem of what our national policy should be in view of this small hazard is not a scientific problem, but a sociological, or a moral one. I think from these considerations, most scientists, and in particular those of us who have appeared before this committee agree that weapons testing should be limited insofar as it is possible and consistent with national security, and indeed, if it were possible, that such testing should be completely eliminated.

However, I would like to reiterate a point brought out by Dr. Dunham on the first day of these hearings—namely, that if we are to proceed into the atomic age with the accelerating tempo of development of nuclear energy, we are faced with the inevitable consequence of a continuous world burden of fission product debris, even without bomb tests, and although we can control this debris, from, e. g., a reactor, to a large extent, a certain irreducible minimum is bound to find its way into the soil and food chain and into man. What I am pointing out is that, bombs or no, we are inevitably going to live with man-made radiation in our bodies. Accepting the opinion that any radiation is dangerous or at least undesirable, it seems to me that a major research effort should be directed at keeping the hazard of fission debris at a minimum. Since internally deposited Sr–90 is generally agreed to represent the greatest long-term hazard, a major component of this problem is to keep the human burden of Sr–90 at a minimum for any given amount of fission. Or, in other words, how can we keep bone deposition of Sr–90 as small as possible and how can we keep the relative body elimination of Sr–90 as great as possible?

May I reiterate that this study is basic no matter what direction the atomic age may take if we accept the philosophy that all radiation is harmful.

---

[1] Date and place of birth: February 26, 1922, Gladwin, Mich. Education: Bachelor of science in chemistry, Wheaton College, 1943; master of arts (physical chemistry), Princeton University, 1947; doctor of philosophy (biological chemistry), University of Michigan, 1951. Work history: Research assistant, Manhattan project, Princeton University, 1943–46; teaching assistant in chemistry, Princeton University, 1946–47; instructor in chemistry, Taylor University, 1947–48; research assistant in biological chemistry, University of Michigan, 1948–49; teaching assistant in biological chemistry, University of Michigan, 1949–51; fellow, Public Health Research Institute of New York City attached to the New York University Research Service, Goldwater Memorial Hospital, 1951–53; research fellow, Columbia Research Service, Goldwater Memorial Hospital, 1953–55; research associate, Lamont Geological Observatory, Columbia University, 1955–. (Submitted by witness.)

Before discussing in some detail what I feel should be done in this area, may I note that, of course, another important problem in which study should be continued and probably expanded is the problem of more precisely defining the physiological hazard per unit of radiation or per sunshine unit of Sr-90 with regard to such things as the genetic effects, leukemia, bone cancer, and life shortening, so that the degree of danger may be properly evaluated. Since the need in this area was brought out in testimony 2 days ago, and since it is outside of my sphere of activity, I will not discuss it further, except to say, that whatever the effects due to the presence of Sr-90 are, we can presume that they are proportioned to the Sr-90 concentration or approximately so, so that the basic practical problem remains one of reducing the human Sr-90 burden.

Now, if we are going to study the reduction of the body burden of Sr-90, and how this may be achieved, it is of initial interest to define what the present level is. This was dealt with by Dr. Kulp last week and I think the situation on this point is quite well in hand. We have been measuring Sr-90 in human bone samples for almost 4 years, and we now have a worldwide sampling network of over 25 stations sending us samples. We know what the average value for adult man is. We know that the young child is about five times this value. We have been able to follow the increment in Sr-90 in human bones from year to year. There are a few soft spots here that should be filled in. The sampling program should be expanded, particularly in primitive areas where because of low soil concentration of Ca and an exclusively local diet we may find higher values. Another problem is distribution and variation within a skeleton. We are currently attacking this problem through the extensive sampling and whole body determinations of 200 cadavers obtained through the cooperation of the New York City medical schools. We urgently need more information on children's skeletons, but such is difficult to obtain for obvious reasons.

Besides measurements in the bones it is of interest and importance to know the concentrations along the early stages of the biological chain—namely the foodstuff, and the soil. I feel here that the program might be stepped up somewhat particularly with regard to the food monitoring. Although milk has been followed quite adequately, other foodstuffs, to my knowledge have not. It seems to me that these food supplies should also be carefully monitored. Soil data should be extended, particularly in foreign locations.

Now to come back to what I initially stated to be, in my opinion, the key practical problem. How might we reduce the human skeleton deposition of Sr-90 for a given soil concentration of the isotope? We look for ways to block the Sr-90 transmission along the various steps of the biological chain. For completeness I'll just mention two possibilities which I haven't studied, but which have been considered, and which might be considered in the future. One is to bind the Sr-90 in the soil so that it cannot enter the plant. The other is to remove the Sr-90 selectively from the food before human consumption, which seems practically impossible, except perhaps from milk. Let us then consider the problem of minimizing the bone deposition for a given concentration of Sr-90 in the food. Considerable experimental work of this nature has been conducted by Dr. Laszlo in which he studied tracer doses of the short lived isotope Sr-85 instead of Sr-90.

Let me briefly explain the use of Sr-85. Sr-85 is another radioactive isotope of the element of strontium. It differs in that it has a relatively short half life of 65 days compared to the 28 years of Sr-90. We expect the Sr-85 to behave chemically and biologically in a manner identical to Sr-90—such a principle being well established and indeed the basis of a tracer work.

What Dr. Laszlo does is to conduct what we call a balance study; i. e., he carefully measures the amount of Sr-85 which the person ingests, and the amount which is excreted over a period of time in order to determine the net amount retained. He has found that certain agents, specifically, Ca gluconate, some chelating agents, and ammonium chloride reduce the net amount of strontium retained in the body.

From a practical standpoint this work has suffered from two difficulties which I think we can now correct: (1) The number of patients who are candidates for Sr-85 administration is strictly limited and (2) the Sr-85, being given over a short interval of time, is not distributed within the bone in the same manner as the Sr-90, which has been ingested continuously in small quantities for years, so that the results are not completely comparable.

We can now obviate the limitation and get at the precise problem since the level of Sr-90 in the food which man eats and the excreta which he eliminates

is sufficient to be adequately measured. Thus we can now study Sr-90 balance directly in humans and, having determined what the net retention is under normal conditions, we can determine to what extent the net retention may be reduced by control of diet and by various prophylactic and therapeutic measures.

May I add that although it is possible to conduct such experiments on ourselves, and we at Lamont have just completed the dietary phase of such an experiment, it is most practical for the most part to conduct such a study in a hospital metabolic ward such as Dr. Laszlo maintains. Such an extended study is contemplated for the near future.

In conclusion I would like to add that in my mind the extensive study of fallout points up a related problem with which we should all be concerned. If we agree, as we do, that it would be desirable to reduce the present fallout burden from Sr-90, then if we are to keep our proper perspective it seems that we should be even more concerned with other much greater sources of radiation around us that might be reduced. Since it is true that living in a brick house versus a wooden house may give a person an additional radiation equal to 20 times that currently received from Sr-90, should we not be concerned with investigating how one might reduce the background from these particular building materials, or the use of adequate substitutes with less radiation to take their place? If a chest X-ray may give 50 times the radiation currently received from Sr-90 in a year and a fluoroscopic examination will give over a thousand times this amount, should not these things be more rigidly controlled, the practitioner and the layman alike better informed as to their hazards, and basic research conducted so that these necessary medical tools may be used with a minimum of radiation? I realize that in the case of the X-ray, some such work is being done, and I'm not saying that the Atomic Energy Commission should get into this area. In fact they probably should not, but I am merely attempting to again put the fallout problem in perspective by noting that these are still much greater risks even in the field of radiation. Of course the fallout hazard still has the peculiar moral problem in that a person may choose whether or not he'll have an X-ray or live in a brick house, whereas in the case of fallout, there is no place to hide.

Dr. Schulert. First of all in the statement I have given the point of view, which is my point of view, that although as has been mentioned there is a considerable area of disagreement which has been evident during these hearings, yet there are some basic general areas of agreement, and we ought to emphasize what these areas of agreement are, and what should be done on the basis of what we do know.

I think we all agree that first of all—this is axiomatic at this point—a definite hazard does exist.

Point No. 2 is that this hazard, though it does exist, is very small compared to the effects of the natural radiation which has always been with us.

I might also interject here, in view of what has been said, that this hazard is small in my estimation and even if we stop bomb testing, we will still have the hazard to some degree due to reactors and so forth. In the industrial use of energy one can control the fission debris largely; yet there is a small irreducible minimum which is bound to get away and get into the human body.

If we take the philosophy that any radiation is hazardous and should be reduced, if possible, then this problem is with us, and the basic research which I will mention today is of importance. Of course, if tests continue it is more important; if nuclear war ensues it is very vital to the life of many people and possibly the Nation as a whole.

Then it seems the basic problem is twofold. Again I am being very axiomatic. First of all to define the hazard, and second of all, to reduce this as much as possible.

In the area of defining the hazard, the first thing might be to determine how much radiation exists. I think again we agree that

the principal hazard is the internal deposition of strontium 90. So the most important phase is to determine just how much strontium 90 is in the human body.

I think on this score we are in fairly good shape. This may sound like boasting since our Lamont Laboratory has been engaged in this phase. I should for the record also indicate that this was underway long before I came to Lamont and I am here in the absence of Dr. Kulp to take his place, and it is more of his show than mine, actually.

We do know pretty well—we have talked about the various uncertainties today—as to how good we know the data and how exact they are. We do know the average concentration of strontium 90 in humans. We know it in adults. I would say we know it to a factor of at least 1.5. We do know that the concentration in children is about 5 times this number from zero to 4 years old. We have been able to follow the increment from year to year. We have gotten some information—perhaps not enough yet—on the geographical variation in this concentration.

Representative COLE. Doctor, would you mind my interrupting?

Dr. SCHULERT. No, go right ahead.

Representative COLE. When you say you do know the concentration in children up to 4 years is 5 times this amount, what amount do you mean?

Dr. SCHULERT. The amount that is present in adults from 20 and above.

There are a few soft spots which I might fill in here. I think we need to expand the program particularly in primitive areas where, because of low calcium in the soil, and a local diet, we might find people with somewhat higher strontium 90 concentrations than the average. We are striving very much to get more data on the bones of children because this is the most important factor, since they are the higher values. As you might imagine, this is the hardest thing to do. We realize it is a rather grim problem to get bones at autopsy from children. The data is more limited here than we would like.

There also remains a little more work to be done on the correlation of the bone data with the data from the diet. I was made aware of this yesterday. We have bone samples from Chile, and we have learned at these hearings that the fallout comes down with the rain. Therefore, Chile, having very low rainfall would be expected to have a low amount of strontium 90 fallout, and it does. Dr. Alexander of the United States Department of Agriculture points out that Chile gets its milk from Wisconsin—dried milk—and this is their main source of calcium (and also strontium 90), and thus their bone concentration of strontium 90 is not as low as one might expect from their soil data.

Representative COLE. Doctor, on the question of milk, you have indicated the principal element of hazard is the strontium 90 and the method of being exposed to that hazard is ingestion. I think you will agree that the consumption of milk is probably the one single item of diet which contains the greatest concentration of this element.

Dr. SCHULERT. Yes.

Representative COLE. I am curious to know, and perhaps you cannot answer, whether there is any body of medical opinion whatever which feels that this degree of hazard of strontium 90 in milk is of

such size as to warrant discouragement of the consumption of milk by growing children?

Dr. SCHULERT. This raises an interesting point. It is true that even the average adult—and we have gotten the figures from many countries on this; do not ask me how many because I do not know offhand—in most places a good deal more than half of your calcium and therefore the strontium 90, we presume, comes from the milk. However, it is also true that the concentration of strontium 90 per gram of calcium is lowest in the milk. That is due to the fact that the cow very fortunately fractionates against the strontium 90. So that the milk that a cow produces has only about one-seventh the strontium 90 per gram of calcium that the cow's diet consists of.

We feel that the important number is the strontium 90 per gram of calcium due to the fact that they go together in the body. Therefore, I would say that the best place to get your calcium (and your strontium 90) is in the milk.

Representative COLE. You still have not answered my particular question. I say maybe you may not know whether there are any doctors of any considerable number or slight number who feel that this content of strontium 90 in the milk is of such amount as to warrant parents to find some substitute for milk.

Dr. SCHULERT. I do not know of any. As I tried to indicate, this would be bad advice. It is better to get your calcium from milk than other food sources, unless you are thinking of synthetic sources.

Representative COLE. I do not know what the alternative sources would be.

Dr. SCHULERT. From any natural source the milk would be the best source of calcium and it has the lowest amount of strontium 90 per gram of calcium.

Representative COLE. Of all the foodstuffs?

Dr. SCHULERT. Of all the foodstuffs we measured.

Representative HOLIFIELD. But it does have more calcium than any other foodstuffs.

Dr. SCHULERT. Yes.

Representative HOLIFIELD. And, therefore, the effect is that although it has less per gram of calcium, it has more in its totality than other foods.

Dr. SCHULERT. That is right.

Representative HOLIFIELD. Therefore, the child should have the milk to get the calcium for his bones and in getting that he must take in an unusual amount of strontium 90, more than he would if he used some other foods?

Dr. SCHULERT. No, you have to have a certain amount of calcium in your diet. I forget the figure. Maybe it is 10 grams. I don't know. If you have to have 10 grams of calcium, you better get it from milk because you will have less strontium 90 for this 10 grams of calcium than from other food.

Senator ANDERSON. I hope we do not leave the impression that milk is not still one of the finest foods for a child.

Dr. SCHULERT. That is right.

Senator ANDERSON. With or without regard to the dangers of strontium 90, there is no finer food in the world for children.

Senator JACKSON. Let us not limit it to children.

Senator ANDERSON. I know what Congressman Cole was trying to get to. In these discussions of how much strontium 90 there might be in milk, somebody might read it and say "I better be careful how much milk my child can absorb." I am completely out of the dairy business. I have sold all my dairy cows, so I am speaking as a disinterested witness. Surely there is nothing in the world that will do the child as much good in the formation of the good solid bone as the constant drinking of sufficient quantities of rich milk. I am very happy that Mr. Cole brought up this question so that before this hearing adjourns we could insert in the record firmly the fact that a child can drink all the milk he wants to all day long and not suffer from strontium poisoning so far as anybody now knows.

Representative COLE. I am very happy that the Senator has emphasized this point. I no doubt was derelict in accepting the doctor's answer with the simple word "no." He said he knew of no doctor who was concerned about the strontium 90 in the milk.

Dr. SCHULERT. You said concerned or was the suggestion that we avoid milk?

Representative COLE. Concerned.

Dr. SCHULERT. Concerned, certainly.

Representative COLE. I meant concerned to the point where they would recommend discontinuance or lessening of consumption.

Dr. SCHULERT. To correct the record, the calcium requirement for a day is 1 gram and not 10.

Senator JACKSON. Do you feel that you can make any kind of prediction now as to what will happen to people as far as strontium 90 is concerned if testing continues at the same current rate?

Dr. SCHULERT. In my prepared statement, and I can say it here——

Senator JACKSON. This is a factor that is not in the natural background. That is why I am asking this question. This is a new element.

Dr. SCHULERT. That is right.

Senator JACKSON. Could you tell us what in your best scientific judgment is apt to occur assuming that testing continues at the same rate, and that the strontium 90 continues at approximately the same rate, as a hypothetical matter?

Dr. SCHULERT. This has been discussed in the hearings before.

Representative HOLIFIELD. The Chair was going to say that this subject was treated exhaustively yesterday in the conference. I have no objection to the question.

Senator JACKSON. I was asking his opinion.

Dr. SCHULERT. It is my feeling that we can compare strontium 90 radiation at least to cosmic radiation, because the energy is roughly the same. To the other natural background it perhaps makes some difference. But the strontium 90 radiation today is about 2 percent of normal background. If testing continues at the present rate, it is calculated that this will go up by a factor of about 8 ultimately. So that this would make it 16 percent of the normal radiation.

Senator JACKSON. What about bone cancer? What is going to be the pattern?

Dr. SCHULERT. Whatever the effect of natural background is today, this would be increased by 16 percent. You can make certain assumptions as to how much bone cancer is due to natural radiation, and this

is uncertain, but whatever the effect is, it would be 16 percent greater. That is the way I look at it.

Senator ANDERSON. I have one question I have been wanting to ask with reference to this. The chart shows that 98 percent of the total radiation is background, and 2 percent may be accumulation from testing and other things. Is there a possibility that the 98 percent may not be as destructive as the 2 percent? By that I mean, is there a possibility that we may have developed through thousands of years a tolerance to cosmic rays that we do not have to strontium?

I see some shaking of heads, but nonetheless I recognize that when we first put out DDT, it was very effective for certain types of insects. Gradually they have developed quite a tolerance to it. We can go through a whole list of remedies and new devices that we have taken, such as penicillin in the human, and the human develops the situation after a while where his diseases do not respond to penicillin, because a tolerance has been developed to it. Could it be that over thousands and maybe millions of years of existence humans have become accustomed to cosmic rays, and therefore are not damaged by the natural background radiation to the same degree that they are bothered by this wholly new substance, strontium 90, that we never knew until 1945?

Dr. SCHULERT. I think in science in general, and particularly in biological science, it is difficult to state anything with absolute certainty. A scientist thinks in terms of probabilities. My own opinion is that if the energy of the cosmic radiation is very close to that which we get from strontium 90, if we have accustomed ourselves to radiation from cosmic ray, we have also accustomed ourselves to the radiation from strontium 90, there would be no added factor.

How sure am I? I can only guess, and I can say I am 99 plus percent sure of this. Since the energies are not exactly identical, it is possible that this precise energy of strontium 90 could hit a vital enzyme in a very special way to break a very critical bond and be much more hazardous. I say the chance is one in a thousand or less. This is the best I can do.

Senator ANDERSON. I realize that nothing is provable, perhaps, with reference to this, but it does seem strange that for a long, long time we have stressed the benefit of sunshine. I recall when I first went to the Southwest suffering with tuberculosis the very first thing the doctor stressed to me was that sunshine was going to be my great curative power. We have had testimony that all types of certain rays—I am not talking about cosmic rays, but strontium 90 and others—may be harmful. I am wondering if natural background radiation is also harmful because we have been talking about living in the sun. If you look at the population statistics, there is a tendency in this country to move into the more sunny States. I just wondered if it is not possible that the human being has not developed a tolerance to sunshine that perhaps makes it beneficial to him. It is a matter that probably is not of importance. I wondered why we worried about strontium 90, if we are worried, and I am, if only a minute particle of radiation we are now receiving and such a large part is already natural background.

Dr. SCHULERT. I share your reaction to the fact that so much is made of the fallout of strontium 90 when the natural background we have

about causes much more radiation. In fact, in the conclusion of my remarks, I do bring out the fact that I think this discussion of fallout should remind us of more important radiation hazards. If it is true that living in a brick house today on the average will give you 20 times the radiation that our present load of strontium 90 will give us, is it not important to try to change our technology to either get this radiation out of the bricks or find substitutes for the brick? If it is true that the average chest X-ray will give you 50 times the radiation that you get from strontium 90 in a year today, and if a fluoroscopy gives you better than a thousand times, should not these be more rigidly controlled? Shouldn't both the practitioner and the layman be educated, and shouldn't research be done so that these things can be reduced to a minimum, still consistent with their need in medical practice?

I think this is true and the people get frightened about fallout and forget the fact that they have had six X-rays in the last 3 years, or had a fluoroscopy and don't worry at all about it.

Representative HOLIFIELD. You may proceed.

Dr. SCHULERT. The other area of defining the hazard, if we confine it to strontium 90, which is the principal hazard, after we know this level, what will the physiological effects be. This has been dealt with in earlier testimony this week. This is an important problem. Of course, research should be continued so we can define as well as possible what the physiological hazard is.

From what I gathered earlier in the week, these things are known to a degree. The degree is not good. Perhaps it is a factor of three. This is much better than knowing nothing about it. We know it to a degree, but it is important to define the degree more precisely. Then going on to trying to reduce the hazard, there are a number of aspects we can consider along this line. Principally again if we stick to strontium 90, how do we reduce the amount of strontium 90 that remains or finds its way to the bone for a given amount of strontium 90 which is released or finds its way into the soil.

If we consider the strontium 90 in the soil, there may be ways to reduce its uptake by plants. This has been considered and it is a tough problem. Once it gets into the food there may be ways to get it out of the food in some instances, but the only example I can think of, is the case of milk. It is possible to take the strontium and calcium out of milk and replace your calcium so that you have milk with no strontium 90.

This is, I am sure, very expensive and technologically it would be very difficult to do on a routine basis.

I would like to confine my remarks primarily to the fact that given a certain amount of strontium 90 in the food, how can we reduce the amount that lodges in the bone. There has been some study on this. Dr. Laszo, the chief of the division of neoplastic diseases at Montefiore Hospital, has studied this problem. He has studied the problem in patients who have received for medical purposes strontium 85. Strontium 85 is another isotope of the element strontium. It differs by virtue of the fact that it has a physical half life of only 65 days whereas strontium 90 has a half life of 28 years. We would expect the strontium 85 to behave chemically and biologically in the manner identical to strontium 90. In fact, this is the basis of all tracer work,

and has been well established, I think. Therefore, we can assume that this is true, and use strontium 85 in our experiments.

What Dr. Laszlo has done is to run what we call a balance study in patients, and the balance study involves the careful measurement of the ingestion of the material, strontium 85, and then a careful measurement of its elimination. Thus if you take the amount ingested, subtract the amount which is eliminated, you have the net uptake by the body. So our problem, then, resolves itself into how can we make this net uptake as low as possible.

Dr. Laszlo and others have found that you can do this to some extent by administering certain therapeutic agents, such as calcium gluconate, chelating agents, ammonium chloride, and others. There are two difficulties, I should say, with the experiments.

One is that these are in hospital patients, and the number of hospital patients who are candidates for strontium 85 administration are strictly limited. So it is a very limited study.

Secondly, when we test this removal we test the removal of strontium 85 which is administered over a short period of time, and this is not the same as testing the removal of strontium 90 which has been ingested in small quantities for a number of years. So the results are not directly comparable.

I think we can now obviate these difficulties because at the present level of strontium 90, it is now possible to measure directly the strontium 90 intake of an individual and his excretion, so that we can do this on you or I or anybody, and having found the net retention under today's conditions, then try various agents to reduce this net retention.

I should add, however, that although you can do it on yourself, and I can do it on myself—in fact, our Lamont group has just completed a dietary phase of such a study, although we don't have the numbers as yet—for the long haul it is much more convenient, shall I say, to do this on hospital patients in a metabolic ward. Shall I say it is socially inconvenient to carry around a suitcase.

So we plan to expand our studies in this direction, not only getting the net retention under present conditions and studying them with various prophylactic and therapeutic agents, but this will give us direct results on this discrimination factor which has been bandied back and forth, another factor which should be known with more precision.

If we can actually do the discrimination under normal conditions with strontium 90 and common calcium, this should give us the answer in this area.

I believe that concludes my remarks.

Representative HOLIFIELD. Thank you very much, Dr. Schulert.

Senator JACKSON. Thank you. You have presented a very good statement.

Representative HOLIFIELD. Are there any comments on Dr. Schulert's statement that anyone would care to make at this time?

Dr. DUNHAM. I am only glad to say that I am happy he was given the opportunity to tell you of the painstaking work involved in these discrimination factors.

Representative HOLIFIELD. Then we will have the Public Health Service witnesses on next. We have Dr. LeRoy E. Burney and Dr. James A. Shannon. Before they present their statements I will insert

in the record at this point a statement from Dr. Henry Blair, director, University of Rochester Atomic Energy Project and his associates.

(The matter referred to is as follows:)

THE UNIVERSITY OF ROCHESTER,
SCHOOL OF MEDICINE AND DENTISTRY,
Rochester, N. Y., June 10, 1957.

A SCIENTIFIC STATEMENT TO THE JOINT CONGRESSIONAL COMMITTEE ON ATOMIC ENERGY

(Atomic energy project—Administered by the department of radiation biology under contract with the United States Atomic Energy Commission)

Mr. Chairman, the following statement represents the considered scientific judgment of the undersigned relative to one of the directions in which we believe the research program in biological and medical sciences dealing with radiation effects should be oriented for the next 10 to 20 years.

Increased emphasis and support should be afforded to long-term studies of radiation effects in longer lived species of animals such as dogs and monkeys whose general physiology and life span more closely approximate those of man.

Much of the present discussion and difference of opinion concerning the biological hazard of atomic fallout and the hazard of exposure to ionizing radiations result from the fact that data from which one can confidently draw conclusions which potentially affect the future of man and of our biosphere are sparse. Many of the available data are based upon painstaking attempts to reconstruct the conditions under which humans were accidentally exposed to toxic materials as long as a quarter of a century ago. There are obvious limitations to the reliability of such data. Other data are based upon careful experimentation with laboratory rats and mice. As useful as the information obtained in studies of such short-lived animals has proven to be, one must be extremely cautious in extrapolating such information to problems affecting man.

By way of perspective we might note that a life-span study using mice requires 3 to 4 years from inception to completion. Similar studies in the laboratory rat may require 4 to 5 years to complete. Studies in longer lived species such as the dog and monkey, whose physiology and life-span characteristics make them more nearly comparable to man, may require from 7 to 15 years for completion.

It is only when long-term studies, some of which are now in progress, have been completed and the information analyzed will we be able to assess with confidence the influence of atomic energy upon man's biological future.

Scientists are somewhat hesitant to undertake such studies for two very important reasons:

1. Such chronic experiments are extremely difficult to perform and sometimes may appear to be impossible to complete. Undertaking these experiments may involve an investment of 5 to 10 years of a man's time before significant scientific contributions appear. Unfortunately a scientist is judged frequently by his immediate scientific productivity and not necessarily by what he might contribute many years hence.
2. The scientific hazards of long-term investigations are of such a nature that even after many years of intense and careful work the experiments may "blow up" as a result of disease or epidemics or accidents in the experimental colony.

Thus the scientist who undertakes work of this nature takes two deliberate and calculated risks—the probable decrease in immediate scientific productivity upon which advancement depends; and the possibility that the experiment may never answer the questions it is designed to answer.

Laboratory program directors and responsible scientific administrators support long-term programs with some trepidation, because such programs are extremely expensive to support and tend to reduce the flexibility of a laboratory in pursuing important shorter term objectives. The nature of fiscal support of research is such that a minor fluctuation in the level of support afforded a laboratory which has long-term research commitments can wipe out much worthwhile short-term research, whereas a substantial budgetary fluctuation may wipe out partially completed work involving many years of scientific effort.

We stress the need for balance and continuity in the support of fundamental and applied research of a short-term nature and research of a long-term nature.

To permit one type of research to prosper at the expense of the other is to jeopardize scientific progress.

Some of the problems resulting from exposure to radiation which are subject to systematic attack by long-term investigations are the following:

1. The relationship of radiation exposure to somatic and genetic mutation.
2. The factors influencing development of cancer and the experimental therapy of cancers.
3. The aging process, whether aging results from exposure to ionizing radiation, exposure to toxic chemical agents, or to natural causes.
4. Fertility and sterility.

The above concepts and opinions are based upon many years of personal experience and observation of both the physical details of performing scientific research and in administrative responsibility for broad programs.

We believe that a statement by the members of the Joint Committee on Atomic Energy affirming its belief in the necessity and desirability of performing long-term animal experiments in the broad fields of radiation effects, carcinogenesis, and cancer therapy, of the aging process, and of genetics would have a widespread and beneficial effect upon both the scientists who must eventually perform this research and upon the public as a whole, whose concern about these problems is already evident.

HENRY A. BLAIR, Ph. D.,
Director, Atomic Energy Project and Professor of Physiology.
HAROLD C. HODGE, Ph. D.,
Chief, Division of Pharmacology and Professor of Pharmacology and Toxicology.
WILLIAM F. BALE, Ph. D.,
Chief, Division of Radiology and Biophysics and Professor of Biophysics.
JOE W. HOWLAND, Ph. D., M. D.,
Chief, Medical Division, and Professor of Radiation Biology.
LAWRENCE W. TUTTLE, Ph. D.,
Chief, Radiation Toxicology Section, and Assistant Professor of Radiation Biology.
GEORGE W. CASARETT, Ph. D.,
Assistant Professor of Radiation Biology.

Representative HOLIFIELD. Dr. Burney, we are happy to have you before us again. Would you like to proceed with your statement?

STATEMENT OF DR. LEROY E. BURNEY,[2] SURGEON GENERAL, ACCOMPANIED BY JAMES G. TERRILL, JR., CHIEF, RADIOLOGICAL HEALTH PROGRAM, PUBLIC HEALTH SERVICE, DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE

Dr. BURNEY. Thank you, sir.

Mr. Chairman and members of the committee, it is a privilege to appear before this committee, and I do appreciate, on behalf of the

[2] Date and place of birth: December 31, 1906, Burney, Ind. Education: Butler University, Indianapolis, Ind., 1924–26; Indiana University, bachelor of science, 1928; doctor of medicine, 1930. Passed Indiana State Board of Medical Examiners, 1930. Rockefeller fellowship in Johns Hopkins University School of Hygiene and Public Health, 1931–32, doctor of medicine in public health. Work history: Interned at U. S. Marine Hospital, Chicago, Ill., 1930–31; commissioned in Regular Corps of the Public Health Service, 1932; established first mobile venereal-disease clinic service in Brunswick, Ga., 1937–39; Assistant Chief, Division of States Relations, Public Health Service, Washington, D. C., 1943–44; detailed to Navy for 5 months in 1944 and sent overseas by War Shipping Administration to investigate and determine effective measures for diminishing amount of communicable diseases in various Mediterranean ports, especially venereal diseases; director of district No. 4, Public Health Service, New Orleans, La., 1945; secretary and State health commissioner, Indiana State Board of Health, on detail from the Public Health Service, July 1, 1945, to August 1954; Assistant Surgeon General and Deputy Chief, Bureau of State Services, Public Health Service, August 1954 to 1956. Recess appointment as Surgeon General, Public Health Service, August 1956. Membership: American Medical Association, Indiana State Medical Association, Indianapolis Medical Society, fellow of American College of Physicians, fellow of American Public Health Association, past president of State and Territorial Health Officers, conference of State and Provincial Health Officers, Indiana Public Health Association, founders group and trustee, American Board of Preventive Medicine, regent for region 4, American College of Preventive Medicine, Commission of Chronic Illness. (Submitted by Department of Health, Education, and Welfare.)

Public Health Service, an opportunity to discuss briefly the deep interest which the Public Health Service has in the subject of radiation and radioactive fallout, and the activites in which we are engaged.

As the principal health agency of the Federal Government, the Public Health Service is concerned with all those factors in our society which affect the health of people. We in the Service believe—as do our colleagues in public-health work throughout the country—that the emerging and challenging problem of radiation deserves the most careful study and attention. I believe two essential points have been brought into focus:

The first is the great increase in sources of radiation as a result of the accelerating use of nuclear energy for all purposes—military, industrial, and scientific. This will require an acceleration in radiological health research and in the development and application of public health control measures.

The second point is that the varying views that have been expressed by scientists illustrate the lack of definite, generally accepted knowledge about the effects of radiation on human health. It is clear that we do not yet know the full consequences of chronic low level exposure. Geneticists have raised the question of the genetic effect of radiation on future generations.

What has been the role of the Public Health Service with respect to the problem of radiation? What can be done to protect people from its possible hazards and at the same time promote its beneficial uses? What is needed to help State and local agencies which are responsible for health preservation of the public?

In considering these questions, we must keep clearly in mind that health agencies must deal with the total problem of radiation, of which fallout, of course, is a part. For example, the efforts of the Public Health Service in this problem go back over several decades.

In the 1930's, the Public Health Service industrial health personnel shared in the investigation of radium poisoning among painters of clock dials, and later helped solve the problem of safe disposal of radioluminous instrument dials. In 1940 the Public Health Service conducted basic work on radium and X-ray health hazards in hospitals.

Dr. Leonard Scheele, the former Surgeon General, participated in this work, along with Dr. Lorenz, who was mentioned this morning.

Research conducted by the Service staff members contributed significantly to the establishment of human tolerance for radiation and performed other staff work at the Manhattan District project. As a result of these studies, Dr. Egon Lorenz served as a consultant in radiation protection at the Manhattan District. Early in the development of mass X-ray programs, the Service developed techniques for safeguarding the health of the operators of X-ray machines. In 1948 the Service set up a branch to conduct training and investigations in the growing field of radiological health. That branch has been active in providing services to the States in this field.

In addition, the Public Health Service has carried out for the Atomic Energy Commission and Joint Task Force 7 the monitoring of levels of radioactivity at the Nevada and Pacific Proving Grounds. We have presented a technical paper on this activity for your records. (See statement of James G. Terrill, Chief, Radiological Health Program, USPHS, p. 328.) In this activity, we have concentrated on

measuring the radiation received by people in the offsite test areas and on studying the means to reduce exposure. We have also studied reactor waste treatment and discharge problems in cooperation with the Atomic Energy Commission.

In sum, therefore, our concern has been with the total radiation exposure of people, whether the source is natural background, medical equipment, nuclear reactor plants, or weapons testing programs. We have undertaken to discover how much and what kinds of radiation emanate from the various sources and how each affects human beings.

The problem is complex. Ionizing radiation, for example, is an important tool in medical diagnosis and treatment, and each year helps conserve the health of thousands of people. Yet it can obviously cause undesirable and sometimes dangerous effects and, if not used with utmost care, can produce, for example, the cancer it is employed to cure. Thus public health agencies are faced with the problem of promoting the maximum use of this valuable tool and at the same time of developing protective measures against the potentially harmful effects. The deceptive latent period between exposure and effect, the cumulative nature of the action, and the difficulties in measuring radiation have commanded the attention of health workers throughout the Nation.

The National Academy of Sciences has said that the healing arts probably constitute the largest single manmade source of external radiation at the present time. The fact that exposure from other sources is on the increase makes it necessary to reexamine and reassess the use of radiation for research and for healing purposes. Exposure levels from a given source which might have been acceptable in the past may now—or in the future—become hazardous when added to the exposure from other sources.

Turning now to the specific problem of fallout, there seems to be general agreement that the principal long range hazard from weapons testing is through the production and assimilation of strontium 90. The most significant question in the strontium picture is the maximum permissible concentration for human beings. This aspect of the problem is further complicated by the fact that children probably assimilate strontium to a greater degree than adults because their bones are growing, and the rapidly growing tissues of the child are more susceptible per unit of radioactivity. The current concern with this radioactive element must not preclude, however, the continuing study of other radioactive elements, either alone or in combination.

Along with many other agencies we in the Public Health Service recognize the potentialities of the proportional or linear relationship of radiation effects to dosage, particularly with regard to genetic, cancerogenic and aging effects. Pending further evidence, we believe that the recommendations of the National Committee on Radiation Protection represent a reasonable balance between radiation effects and exposure. There is a great need, however, to measure existing radiation levels accurately and to resolve in a more definitive way the biological relationships involved.

The question of biological relationships will be discussed in greater detail by the Director of the Public Health Service's National Institutes of Health. But I do wish to point out now that we are vitally interested in obtaining better data on the fundamental relationships

beween radiation and man. We do not expect to obtain conclusive data in this area in a short period of time. Satisfactory answers will require careful and extensive studies.

Much of our current information on the effects of radiation, particularly the delayed effects of low-level radiation on human beings, is extrapolated from studies with animals. These studies indicate that the damage produced from such exposures is generally similar to diseases and other abnormal conditions already present in the population from causes other than radiation. It follows, therefore, that statistically valid analyses of changes in the incidence of such conditions in the population are needed in order to assess the impact of radiation on man.

A sound scientific basis for collection of data of this type is through epidemiological followup studies of relatively large numbers of people who are incidentally exposed to known amounts of radiation. Studies can be made with groups in certain industries and the healing arts in which the exposure history can be obtained or measured. Epidemiological studies with these groups are fundamental to the problem of obtaining data on which to base realistic, maximum permissible exposure limits, as well as to calculate the risks incidental to any given radiation exposure.

One such study which the Public Health Service is conducting is a long-term followup of the health status of uranium miners on the Colorado Plateau. Several years ago work was initiated to determine the extent of radioactive contamination of the atmosphere in uranium mines and to study and put into effect appropriate control measures. The environmental aspect of this study is continuing, and periodic clinical examinations are being made on more than 1,100 uranium miners. One such clinical examination is now being made on this group of 1,100 miners. Additional information on this study has been submitted to your committee for the record.

Senator ANDERSON. Does that study show anything thus far?

Dr. BURNEY. No, sir.

Senator ANDERSON. They have been mining on the plateau for many years. Have you see anything yet?

Dr. BURNEY. No, sir. We have not found anything in this period of time, but we rather doubted that we would, although some of these people go back to around 10 years of having worked in this area. A large number of them worked in this atmosphere only for 2 or 3 years. With the long latent period we are not surprised not to have found anything.

Senator ANDERSON. Is there any difference in the big Indian area of Utah as compared to the sort of open pit mining that has taken place in the grants area?

Dr. BURNEY. May I refer that to Mr. Terrill here, who has been doing that work?

Senator ANDERSON. I do not care who you refer it to. Is there a difference in the development of exposure inside a mine like the Mivida mine as contrasted with the open mining that Anaconda is doing in the Ambrosia Lake area?

Dr. BURNEY. I would suspect that there is, but I would want Mr. Terrill to answer that question.

Mr. TERRILL. The principal method utilized to lower radiation exposure in the mines is related to ventilation. So the actual concentrations to which the miners are exposed are a function of the ventilation in those mines, as well as the concentration of the uranium ores.

Senator ANDERSON. That is interesting, but does it answer my question? There is no ventilation in the Anaconda open-pit mine. Therefore, I am trying to find out is there any difference in the way a miner is exposed inside a mine of the Mivida nature as contrasted to the open-pit mining in the Anaconda mine?

Mr. TERRILL. Sir, I got the location of the Anaconda mine, but what was the other place?

Senator ANDERSON. The Mivida mine in the Big Indian country in Utah. Take any one. I do not care which one you take.

Mr. TERRILL. They have been relatively small mines.

Senator ANDERSON. They are ventilated?

Mr. TERRILL. Yes.

Senator ANDERSON. Does a miner working in the shaft of that mine with a relatively high uranium content ore, contrasted with work outdoors with the low-grade ore of the Anaconda Co. pick up more harmful radiation? Seventy percent of all known uranium reserves of this country are located where the open-pit method can be used.

Mr. TERRILL. Generally a person who is mining in an open pit would receive less radiation exposure than one who was working in a mine where you are dependent on artificial ventilation. On the basis of field tests the natural ventilation prevents the accumulation of radon and its decay products and thus reduces exposure very significantly.

Senator ANDERSON. Do we have any study which proves that?

Mr. TERRILL. We have a detailed study on underground mines, sir, and I think we have submitted it for the record. We have not studied open pits so intensively because the gross measurements have been so low. All of the details and all the mines that we have investigated have been written up and published in an article by Holiday and others working out of our Salt Lake City field station.

Senator ANDERSON. Does the examination of these 1,100 miners show that they get a relatively larger exposure than those individuals not working in mines, and do we therefore conclude that miners working in the unanium mines need to be rotated more than miners working in a lead, copper, or coal mine?

Mr. TERRILL. Generally they receive more exposure to radioactive materials than other miners.

Senator ANDERSON. I am sure they receive more exposure if they are in a uranium mine than if they are in a coal mine, but what does it do to them?

Mr. TERRILL. That is what the clinical studies are intended to determine over a period of time.

Senator ANDERSON. Then is the answer, We do not yet know?

Dr. BURNEY. The answer is we do not know. In this study, as in similar environmental health programs, we have made use of the cooperative relationships built up through the years with the State and local health agencies. In assessing the health problem, these agencies must consider exposure from all sources of ionizing radia-

tion—weapons, reactors, industry, medicine, and natural background. If the total exposure begins to approach maximum permissible concentrations, it is important that public health agencies seek ways to assess the significance and to apply techniques to maintain exposure at the lowest practicable level.

Senator ANDERSON. In your statement you say the most significant question in the strontium picture is the maximum permissible concentration for human beings, and here you have said something about the maximum concentration.

Dr. BURNEY. We have been using the recommendations of the National Committee on Radiation Protection.

Senator ANDERSON. Do you subscribe to that?

Dr. BURNEY. Yes, sir.

Senator ANDERSON. Did you make an independent investigation of it?

Dr. BURNEY. I can't answer that. We do work with Dr. Taylor and his group on this.

Mr. TERRILL. The Public Health Service is represented on the National Committee on Radiation Protection and all of the data that we collected through our National Institutes of Health or other studies are routinely submitted to the National Committee, and considered by it and our membership on it; yes, sir.

Dr. BURNEY. In other words, control procedures to minimize individual hazards should accompany any anticipated increase in radiological exposure.

Through measurement and epidemiological techniques, we should be able to evaluate in the field many of the sources and to obtain reliable estimates of exposure. This should lead to specific and practicable suggestions on ways in which radiation exposure can be reduced. For example, our studies of water decontamination indicate that the most practical method of reducing radiation exposure from water supplies is through adequate waste treatment and through monitoring and bypassing that portion of the water supply which may temporarily contain undesirable amounts of radioactivity. In order to do this, it will be necessary to do more frequent sampling of water supplies to keep track of any increases over normal background radiation.

Senator ANDERSON. When you refer to waste treatment, is there some established pattern of treating wastes?

Dr. BURNEY. We are investigating, again in some instances, with the Atomic Energy Commission and some on our own at the Robert A. Taft Sanitary Engineering Center at Cincinnati, the problem of treatment of industrial wastes or other radioactive waste. As far as I know, there is no economical and satisfactory method at the present time for major sources of nuclear waste.

Senator ANDERSON. I read your sentence again. For example:

> our studies of water decontamination indicate that the most practical method of reducing radiation exposure from water supplies is through adequate waste treatment.

In order to find that out, you must have know what adequate waste treatment was. What was it?

Dr. BURNEY. This would depend on the elements that were present in this treatment. We do know that normal waste treatment, includ-

ing filtration and aeration and even chlorine treatment, does not remove all of the radioactive material. But it does help to a certain extent.

Senator ANDERSON. To what percentage would you estimate aeration would remove the waste?

Dr. BURNEY. I will have to ask Mr. Terrill for the answer.

Mr. TERRILL. Mr. Anderson, we have found that normal types of treatment remove radioactivity only in terms of percentages comparable with other similar chemical substances. In most instances in the radioactive waste treatment we are interested in removing substances by several orders of magnitude. Those orders of magnitude, of course, vary anywhere from your high-level wastes that you have to treat at AEC processing installations on down to relatively low levels of waste that you get either industrially or from medical uses. Special waste treatment methods, such as distillation and ion exchange remove radioactivity by many factors of 10, but these methods are comparatively expensive and don't solve the disposal problems.

Dr. BURNEY. His question was what percentage of removal can we expect from waste treatment.

Senator ANDERSON. That is right. You have a reactor operating at Hanford. It has radioactive wastes. What percentage of the radioactive waste in there could be handled by aeration, as you have suggested? Practically none?

Mr. TERRILL. Practically none.

Senator ANDERSON. You could say that for the other accepted fashions?

Mr. TERRILL. Yes; for normal waste-treatment methods.

Senator ANDERSON. We do have a problem of waste disposal, do we not, that has not yet been solved?

Dr. BURNEY. That is correct.

What is needed, generally speaking, is a program that will be alert to any changes in our radiation environment and that will be ready to institute control measures which may be called for.

In the field of medicine, advances are being made in radiological techniques which result in lower exposures to clinical personnel as well as to patients. A concerted effort on the part of the health professions is needed to control harmful amounts of radiation in connection with diagnositic procedures—and such an effort is already underway.

These are but a few of the areas in which action can be taken. Their effectiveness, however, depends to a considerable extent on the participation by official health agencies and educational and scientific institutions, as well as on the close cooperation of the civilian and military agencies of the Federal Government.

In order to assume their proper roles, States and local agencies—in whom basic responsibility for protecting the health of their citizens rests—need to develop more technical competency in the field of radiological health. The Public Health Service has been able to provide short orientation and special training courses, primarily to States and local health personnel. We have also used our commissioned officers in monitoring radioactivity levels for the Atomic

Energy Commission in Nevada, thus providing firsthand field experience to personnel from health agencies.

To meet the long-range needs of health agencies, we believe it will be necessary for the professional and scientific schools of the country, which provide the basic training for our health workers, to strengthen their programs. Some Federal assistance is being provided through our general public-health traineeship program and through the research grants and fellowship programs administered by the Public Health Service's National Institutes of Health. It is apparent, however, that more specific emphasis will be necessary to provide the number of trained persons required.

In summary, we believe that radiation is a health problem of growing significance. Health agencies are, of course, looked to for leadership and counsel wherever a health problem exists and they must face the problem of radiation as it relates to health with vigor and determination. To do the job will require cooperation among all concerned at all levels of government. The Public Health Service pledges itself to this ideal.

Senator ANDERSON (presiding). Are there any questions?

Chairman DURHAM. Doctor, I am sorry I was not here at the beginning of your statement. What kind of a setup have you got in your department for this type of operation?

Dr. BURNEY. Basically we have two groups that are concerned with this problem. One is at the National Institutes of Health, where research and training in the broad field of physical biology which includes radiobiology has been done for many years, in which research is done within the various institutes—the National Cancer Institute, the Heart Institute, the Arthritis and Metabolic Institute—and also in which grants are made to outside scientific institutions for research in the field of radiobiology.

We have at this present year, I believe, about $2 million worth of grants going to scientific institutions for research in radiobiology itself. Then training programs for training research workers in the various sciences related to radiobiology—biophysicists, biochemists, and similar groups.

Chairman DURHAM. Is that entirely related to the field of radiation?

Dr. BURNEY. Yes, sir. It includes the effects of radiation in production of cancer. It is not entirely on the matter of radiation exposure as we are talking about it here.

Chairman DURHAM. Is all of that information made available to the different State public-health agencies?

Dr. BURNEY. Yes, sir, it is. Then in addition to that, in our field activities we have a very effective relationship with the Atomic Energy Commission and have had for a number of years in working with them on field studies. We have one or more men working at the Oak Ridge Laboratory, on the industrial waste problem that Senator Anderson mentioned, to try to solve that. We are also doing work at our sanitary engineering center in Cincinnati, in trying to evolve methods of disposing of radioactive wastes, and measuring radiological effects.

We are concerned in our air-pollution program as well as our water pollution with developing better sampling techniques, both in air and

water. Of course, radioactivity detection is an important part of that.

Chairman DURHAM. You have full cooperation from the AEC in all matters pertaining to this?

Dr. BURNEY. Yes, sir; we work very closely with them.

Chairman DURHAM. Can you give the committee the amount of money that your agency is spending on this program?

Dr. BURNEY. Excluding the National Institutes of Health—as I say, $2 million of those funds is for extramural research grants—Dr. Shannon may be able to tell you exactly how much we spend on our intramural programs. He tells me $250,000 on direct research.

Chairman DURHAM. Do you submit a separate budget for this, Doctor, identified as radiation health hazard?

Dr. BURNEY. No, sir, it is not; it is part of the National Cancer Institute budget, part of the arthritis and metabolic-disease budget. We do have a special Radiation-Study Section which reviews all of the requests.

Chairman DURHAM. This is a growing matter of concern. Have you given any thought to treating this as a separate item?

Dr. BURNEY. We do have, other than our research program at the National Institutes of Health, a separate item for radiological health. That at the present time amounts to $347,000. We requested quite a sizable increase in 1958. The House allowance was not quite what we asked for.

Chairman DURHAM. Would that apply on waste hazards?

Dr. BURNEY. Yes, sir. Research in waste treatment. It applies also to the training of State and local personnel in this area. It applies to the epidemiological studies we are trying to do, and it applies to the technical help we give the States. For example, one State wanted to develop a radiological health program. They had no experts.

They asked us to lend them an expert in the field for 2 years until they could develop their own people. At the end of that 2 years' time, they had their own people. We brought our person back and he is working with us again.

So that is the kind of technical assistance that we give to the States.

Senator ANDERSON. Thank you, Dr. Burney.

(A supplementary statement by Dr. Burney follows:)

STATEMENT TO SUPPLEMENT PRESENTATION BY THE SURGEON GENERAL, PUBLIC HEALTH SERVICE, DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE, BEFORE THE JOINT COMMITTEE ON ATOMIC ENERGY HEARINGS ON THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN

An example of the long-term epidemiological and statistical study needed to better define the effects of ionizing radiation on humans is the continuing evaluation of the health status of uranium miners on the Colorado Plateau. Several years ago work was initiated to determine the extent of radioactive contamination of the atmosphere in uranium mines and to study and put into effect appropriate control measures where needed. The environmental aspect of this study is continuing and the data were reviewed in a recent publication by the Public Health Service.[1]

[1] Control of Radon and Daughters in Uranium Mines and Calculations on Biologic Effects: U. S. Department of Health, Education, and Welfare, Public Health Service Publication No. 494.

Various aspects of the degree of environmental contamination and measures for its control have also been reviewed in other publications.[2 3 4 5 6 7 8]

Armed with knowledge regarding the levels of radiation exposure, and following pilot work during previous years, a full-scale epidemiological followup study was initiated in 1954. At that time, physical examinations were conducted on 1,124 uranium miners in the field, to serve as a baseline for future observations. At yearly intervals since that time, a census has been conducted to define the current status of each individual in the study and this month a series of followup physical examinations will begin. To date, the followup has been quite successful. Although the group under study presents technical problems in followup that are somewhat more complicated than might be true in other groups, primarily because of its somewhat transient nature, approximately 95 percent of this original group have been successfully contacted since their original examination. It is anticipated that by the use of more sophisticated methods which are available to organizations with competencies in the field of epidemiology, this followup rate may approach 100 percent.

To date, it is much too soon to derive any definitive conclusions from this study. Among the reasons is the fact that previous experience,[9 10] has indicated that the damage, if any, might be delayed for many years after the beginning of exposure. The following table indicates the percentages of individuals under study falling in each of several categories with regard to the number of years of exposure to date:

Percentage distribution of miners by years exposure

Years	Percent	Years	Percent
Less than 1	38. 2	4 to 6	14. 4
1 to 2	20. 2	7 to 9	4. 2
2 to 3	11. 6	10 to 12	1. 0
3 to 4	8. 6	13 and over	1. 8

Although this study illustrates some of the problems which one encounters in conducting a long-term epidemiological and statistical study, we believe it also demonstrates the fact that epidemiological studies in this field can be successfully prosecuted.

Dr. Shannon, will you come forward please?

STATEMENT OF DR. JAMES A. SHANNON, DIRECTOR, NATIONAL INSTITUTES OF HEALTH, PUBLIC HEALTH SERVICE [10a]

Dr. Shannon. Mr. Chairman and members of the committee, the Surgeon General of the Public Health Service has emphasized the

[10a] Date and place of birth: August 9, 1904, Hollis, New York City. Education: Bachelor of arts, College of the Holy Cross, 1925; doctor of medicine, New York University, 1929; doctor of philosophy, New York University, 1935. Work history: Instructor in physiology, College of Medicine, New York University, 1932–35; assistant professor of physiology, New York University College of Medicine, 1935–41; guest investigator, physiological laboratory, Cambridge University, England, 1936; assistant professor of medicine, New York University College of Medicine, 1941–42; associate professor of medicine, New York University College of Medicine, 1942–46; director, Squibb Institute for Medical Research, New Brunswick, N. J., 1946–49; special consultant to the Surgeon General, Public Health Service, 1946–49; associate director in charge of research, National Heart Institute, National Institutes of Health, 1942–52; associate director, National Institutes of Health, in charge of intramural affairs, 1952–55; director, National Institutes of Health, 1955–. (Submitted by Department of Health, Education and Welfare.)

need for further research on the problems of radiation. It is in this area, and in the area of scientific training, that the activities of the National Institutes of Health relate to radiation.

The National Institutes of Health, as you know, is a research and training organization within the Public Health Service. We support medical and related research in universities and medical schools through grants which currently total about $90 million per year. We administer a training program which helps support the training of about 5,000 scientific personnel annually. We also carry on basic and clinical research in our own laboratories.

Our contribution to the problems of radiation lies primarily in further exploration, in our own laboratories and through research grants, of the manner in which radiation affects human beings. As the Surgeon General has pointed out, a more thorough understanding of the manner in which radiation affects biological systems is necessary.

The basic research inquiry into the effects of radiation as it relates to health, I believe, can best be approached in the context of physical biology, broadly defined. Physical biology includes the study of the means by which all physical phenomena act within biological systems.

It includes the effect of heat, cold, pressure, light, sound, vibration, acceleration and deceleration, electrical properties of molecules, the movement of material across membranes and ionizing and nonionizing radiation. As a field of study it depends heavily upon modern mathematics and physics and scientific instrumentation.

We share the view of those who believe that physical biology as a discipline will, in all probability, exert a dominant force upon medical and biological research over the coming decades.

Research in physical biology has for some time been a part of the total program of the laboratories of the Public Health Service's National Institutes of Health. We have, in fact, a Laboratory of Physical Biology in which research in some of the areas noted above is now being carried on. This laboratory, for example, has been under contract by the Armed Forces special weapons project in studies dealing with post radiation infections. This collaborative project is still continuing.

Another illustration, in a different field, is found in the contribution of the late Dr. Egon Lorenz of the National Cancer Institute to which Dr. Burney has already referred. His work in the general physiology of radiation effects, including protection against radiation damage, stands as a significant contribution in this field.

The National Cancer Institute conducts a substantial research program in clinical radiology, together with a basic program relating to the biological effects of ionizing radiation.

At the National Institutes of Health, we hope to place the highly specialized research in radiobiology within the context of the broad area of physical biology. For example, we are establishing a panel on mathematics attached to the research operation in physical biology. This panel will work on the applications of advanced mathematical techniques to biological problems, including the use of a large electronic computer in the solution of these problems.

Organizationally, we hope to place research in radiobiology in a single organization—the existing Laboratory of Physical Biology.

We intend to expand this laboratory at a moderate rate, primarily because of problems relating to research facilities and the shortage of scientific manpower in this field.

Research scientists themselves initiate the studies which are supported by NIH grants. Hence there are limits in the degree to which it is possible or advisable to change emphasis in fields of study. Experience has shown, however, that when an area of study is promising, investigators can be persuaded to enter or intensify their efforts. This is done primarily through persuasion by colleagues and a change of research emphasis by free choice. About $4.5 million per year in research grants now supports work in physical biology; of this amount, $1.2 million is for work in radiation biology.

Scientific manpower is in extremely short supply in the entire field of physical biology, including radiobiology. Because this is a relatively new field, fully satisfying career opportunities are few in number. A sound program for strengthening the field of physical biology should therefore encompass the establishment of a number of academic posts with adequate status, stability and income.

Attraction of additional students is, of course, also important, as is the content and vigor of their graduate instruction. There are waves of advance in fields of science which attract people as new and exciting fields open up. Nuclear physics has been one such field. Its immense popularity is shown by the fact that in 1951, 36 percent of all physicists in the age group 25 to 29 were nuclear physicists. Among those in the 50- to 54-age group, only 12 percent were nuclear physicists.

While the distribution of advanced students by field is fixed to a substantial degree by the stage of evolution of a science, this distribution can be affected—without producing accompanying harmful effects—by a carefully considered program.

The Institutes are establishing such a program as part of a total effort to increase the pool of research manpower for medicine and related scientists. Last year, for example, a senior research fellowship program was established. The fundamental objective of this program is to provide stable support for the most promising young investigators in the 5 to 10 years after they complete work for the doctor of philosophy in sciences basic to medicine. This is the critical period when too many younger investigators drift out of research. This obviously results in a loss of scientific manpower. In addition, the medical schools find it difficult to train people of high caliber in the teaching posts available for the sciences basic to medicine.

In fiscal year 1937, about 1,000 postdoctoral and 1,000 predoctoral fellows were preparing for research careers with the aid of fellowship funds of the NIH. In addition, almost 3,000 individuals were in training with the aid of training grants.

Over the past few years, the Institutes have emphasized the significance of training to the future of research in medicine and the related sciences. We are referring here to training not at the highly specialized technical level, but at a high level of scientific competence.

The total training activities of NIH have expanded rapidly. In fiscal year 1956, the appropriation for training activities approximated $17 million, while $33 million was provided for fiscal year 1957.

With this increase, substantial funds will be available to support advanced students in physical biology. Gradually, emphasis will shift

to the problem of recruitment and the problem of the content of training. The problem of motivation of students to study science—a problem which is fundamental to our national scientific effort—is shared by many groups ,and principally the National Science Foundation.

On the other hand, we believe that NIH can help universities set up courses in physical biology which will take students to the frontiers of knowledge. We also believe that NIH can help outstanding men in the field to find outstanding students who have already acquired a sound university grounding in science. Drs. Schmitt and Bolt of the Massachusetts Institute of Technology are working, on this problem in biophysics with the aid of a Public Health Service grant.

In conclusion, I should like to stress our conviction that a soundly conceived and operated research training program is a prerequisite to the successful solution of applied problems of radiobiology—of which the problem of radiation is one. In the field of manpower training we believe that the Public Health Service can make a most significant contribution to resolution of the problems related to radiological health.

Senator ANDERSON. Thank you, Doctor. I am glad to hear of the development of this work. Are there any questions?

Representative COLE. Mr. Chairman, I want to comment just a little bit on the doctor's statement, comparing the number of nuclear physicists in 1951 of the 25- to 29-age group as against those at that time of the 50- to 54-age group. The younger group is 36 percent of the total, and the older-age group is 12 percent of the total.

Frankly, I am not so much impressed by the fact that 36 percent of the total in 1951 were nuclear physicists, although that is encouraging, but I am very much impressed by the 12 percent in the upper-age region. That would lead me to conclude that as long ago as 25 or 30 years ago scientists became interested in nuclear physics as a profession. Is that a fair conclusion?

Dr. SHANNON. No, sir. This field was really opened up fairly widely in the 1930's. I think of the 12 percent of the older physicists who are in nuclear physics now, a sizable proportion of them are in there as a result of what one might call a retread, with the acquisition of new skills. In other words, I do not believe, despite the fact of the upswing of nuclear physics in the 1930's, that a sizable proportion of them entered this field initially. A 50-year-old physicist would have completed his degree in the 1920's. This is far too high a proportion to believe that they originated as nuclear physicists.

Representative COLE. I suspected there might be some such explanation.

Dr. SHANNON. The reason for quoting the figures, sir, is to indicate how one can in a carefully planned course, providing it is an intelligently planned course and makes sense, divert scientific talent without at the same time interfering with individual decisions.

Senator ANDERSON. Are there any additional questions? If not, this concludes what we are doing, with four exceptions. We want to make sure that if there are any closing and final statements that anyone wants to give, that we will not miss them. I particularly want to call on four people.

Dr. Waterman.

Representative VAN ZANDT. Mr. Chairman, may I ask Dr. Burney a question before he leaves the stand?

Senator ANDERSON. Yes.

Representative VAN ZANDT. Dr. Burney, you conclude your statement by saying, "To do the job will require cooperation among all concerned at all levels of government." That poses this question: How active are the several States in setting up some kind of control of radiation and the use of radiation?

Dr. BURNEY. That has been spotty, Mr. Van Zandt. Let me say first that there are several States, New York, California—I don't want to leave out any States, but I am naming those as examples—who have developed some good personnel and have what we would term a good radiological health program. But within the last 12 months there are a large number of other States which have recognized the importance of this problem, which have asked us for help in assigning personnel, or have sent personnel to our courses for training in order that they can go back and set up a program of their own. I would say it has been spotty, but it is growing now in State and local health departments.

Representative VAN ZANDT. With the development of knowledge and its dissemination, are you satisfied with the progress that is being made by the several States in setting up the necessary controls?

Dr. BURNEY. No, sir, but I would like to say that I am not satisfied with what the Public Health Service has done, either. I would not be too critical.

Representative COLE. I have a question of Dr. Shannon. I had to hurry over your statement because I had to answer a quorum call. I happen to be a member of another subcommittee of this Joint Committee that has to do with the problem of shortage of physicists, and so forth. Testimony that we took last year led us to believe that there is a terrific shortage. I am just wondering how long is this shortage going to exist on the effort that is being made today?

Dr. SHANNON. I would say, to pick a figure in years, certainly it will be here with us for at least 5 years. That figure is taken from an appreciation that a graduate degree takes a minimum of 3 years, and even with very active prosecution of programs, a 5-year period is much too short a time to figure that the shortage will have been remedied.

One of the important things is that wholly apart from the importance of physicists to programs in radiobiology, physicists now have a tremendous amount to contribute to the total field of biology and medicine. They are just coming into their own. You will have competition for physicists, biophysicists, physical chemists, and the like, from wholly new areas that were not available to compete for them as short a time ago as 5 years.

It is really an appreciation of this acute shortage which we feel will grow that led us a year and a half ago to mke our first positive effort to provide training opportunities for these university people.

Representative VAN ZANDT. Dr. Shannon, with your knowledge of the overall field, is it proper to say that there is a tremendous amount of enthusiasm?

Dr. SHANNON. Yes, sir.

Representative VAN ZANDT. And the field is attracting a lot of young capable people?

Dr. SHANNON. I will take the "yes" back until I am sure I know precisely what you have reference to. There is a tremendous amount of enthusiasm for entering training as physicists. There is not a proportionate amount of enthusiasm for entering the more restricted field of radiobiologists. There is essentially little in the way of professional training programs. We in the Cancer Institute have been attempting to develop professional personnel along these lines in a very positive way for a 5-year period. We have been wholly unsuccessful. This has led us in the past year to redefine our interest as being much broader than radiobiology, to redefine it in terms of physical biology, where we feel that the career opportunities of sufficient breadth will open up to attract people to them. But at the present time there are not sufficient university posts in the field of physical biology to really attract the brilliant youngster. We feel that the field has to be defined broadly and the research opportunity given which will automatically attract people into the field.

Representative VAN ZANDT. Thank you.

Representative COLE. How long does it take to make a nuclear physicist after he has finished high school?

Dr. SHANNON. Roughly 7 or 8 years. This would be the conventional college course with a 3- or 4-year graduate course superimposed.

Representative COLE. That would lead to a doctorate?

Dr. SHANNON. Yes, sir.

Senator ANDERSON. Dr. Waterman of the National Science Foundation.

STATEMENT OF DR. ALAN T. WATERMAN, NATIONAL SCIENCE FOUNDATION [11]

Dr. WATERMAN. I have no prepared statement, Mr. Chairman. I can, however, make some general comments.

First of all, with regard to the interest of the National Science Foundation in this program, we are, as you know, concerned primarily with basic research and training in the sciences and in that program we do not ourselves conduct research; but we provide support for research by means of grants to institutions for the support of work by scientists on projects selected from these that come to us. In that program we do have in the biological sciences a number of grants that are concerned with research in genetics and related problems, which are basic to the general topic of this committee. When it comes to work which is more directly of the applied nature, then this is not a province of the Foundation. We would leave this to the National Institutes of Health, the Public Health Service, and other agencies.

[11] Date and place of birth: June 4, 1892, Cornwall-on-Hudson, N. Y. Education: Bachelor of arts, Princeton University, 1913; doctor of philosophy in physics, Princeton University, 1916. Work history: Instructor in physics, University of Cincinnati, 1916–18; 2 years military service with Science and Research Division of Army Signal Corps in World War I; faculty member of Yale University in department of physics until 1948, with leave of absence during 1927–28 on a national research fellowship to King's College, London; to Massachusetts Institute of Technology in 1937, and to Office of Scientific Research and Development from 1942 to 1946; appointed Director of the National Science Foundation April 6, 1951, and reappointed April 6, 1957; serves as a member of the Defense Science Board and the Advisory Panel on General Sciences of the Department of Defense, and of the Science Advisory Committee and the Committee on Specialized Personnel of the Office of Defense Mobilization. He is also a member of the President's Advisory Committee on Weather Control; board of directors of the Center for Advanced Study in the Behavioral Sciences; board of trustees of Atoms for Peace Awards and the board of directors of the American Association for the Advancement of Science. (Submitted by Witness.)

That is to say, we are not concerned with research which is aimed at the diagnosis, treatment, and cure of disease; but, rather, a better understanding of the fundamental processes which occur in the body or in nature which have to deal with these subjects.

We have a fellowship program which provides about 800 predoctoral fellowships in all the sciences each year. It is a national program. We also have about 100 postdoctoral fellowships, and we have certain other postdoctoral fellowships for really senior research investigators, and faculty science fellowships primarily for teachers.

In our assistance to training in science, we have 96 summer institutes who select the field of radiobiology, but they are not large in number.

In our assistance to training in science, we have summer institutes which we are financing this summer, whereby teachers of science can get together in their individual sciences for 6 or 8 weeks, for the study of teaching methods and study of research material for teaching use. Six of those summer institutes are conducted and sponsored jointly by ourselves and the Atomic Energy Commission in the field of radiobiology. It is largely to have the teachers informed with regard to this subject.

In addition, we have provided funds to the Atomic Energy Commission for a program at Oak Ridge which will train high-school teachers in instructional methods and send them around the country so that the schools of the country and educational institutions can learn directly about nuclear energy and radiobiology. Those are the activities in our program which bear directly on this program.

The research and training aspects in this whole field are regarded as very important indeed.

With respect to the general subject, I cannot qualify as a research expert in particular fields. However, I am a physicist by profession and for the past 15 years or so have been concerned with the broad features of various aspects of this whole subject, such things as nuclear weapons, nuclear power, fallout, radiobiology, and similar problems.

In the middle of so much discussion, it seems to me, it pays to keep attention on some of the main features and not lose sight of them. This problem that we are dealing with is puzzling for a very fundamental reason, because the two alternatives are not really comparable. On the one hand, one has the national issue of the danger of war and the need to have superiority in the latest weapons. If it were clear that anything we do could establish a clear superiority in a weapon of any kind, and by that act prevent war, I am sure the problem would be much clearer, and the country would do whatever is necessary. Unfortunately, the evidence in these matters is not easy to come by, and the conclusion is very puzzling to make. But this is a national question which involves primarily our own country and the countries of the free world, and is of the gravest importance.

On the other hand, we have the question of fallout and the dangers of radiation. This is much more a personal and individual matter. There are individual reactions to this. Also it applies to all mankind and not only our country.

Furthermore, it involves a type of consideration which in the history of mankind has always been a very serious thing to face: the danger of the unknown. When one realizes a danger he has no

control over, and knows nothing about, to him it is a big danger, much more of a danger than a car running down the street which he can see and thinks he can avoid.

The next thing is that the consequences pointed out by scientists are frankly ugly and repulsive to him, for example, such matters as the effect on future generations. So this becomes a problem which to the individual is much more serious in his mind than many of the ordinary, more dangerous problems we face. That has to be reckoned with.

It has been said before, but bears repeating, that what we are talking about in this fallout danger and other radiation danger is not a new danger. It is a danger that has already existed in the lifetime of mankind. The level of that is quite considerably greater than any new dangers we are talking about. So we are merely talking about adding to the present danger. This then becomes a matter of probabilities, and probabilities are not an easy thing to get clear.

For example, if it were established that carrying a watch with a radioactive dial ran 1 chance in 100 million of proving fatal to the carrier, I suspect that many people would continue carrying watches. There would certainly be a few who would stop at once. On the other hand, if the risk were 1 in 10, probably nobody would carry radioactive dial watches.

The matter of estimation of the probability in this case is a hard thing to do and it reacts differently on different people. To take an illustration which is closer to this problem, we know, for example, that cosmic rays come in to the earth in greater quantities at the Poles than they do at the Equator, due to the magnetic field of the earth. This means that the danger from radiation from cosmic rays is greater at the Poles than at the Equator. Because that is true, does that means that the population immediately should move to the Equator? I think that poses the kind of question we are up against. It is probably true they are safer there, but is it worth it? So one runs into that type of consideration in dealing with the whole question.

I have just one more comment to make and then I would be very glad to answer any questions. While the difficulties in this are great, the promise of future valuable results and data bearing on the problem is also very great. By the evidence you have heard today, there are a number of fields of research that are now being prosecuted vigorously and in capable hands. We can confidently expect that these will produce results. It will be everyone's hope that these results can be speeded up in every possible way. Probably as research goes on, more different methods will occur to us. The power of this kind of research is very great. From our limited point of view at the present time we can see certain areas that are bound to be promising. We know we are going to get more precise information on the basis of which to make decisions and in certain other directions we can find that certain constructive things can be done to forestall the dangers, such as some treatment by which the body can deal with these menaces more efficiently. However, at any given time there are things that are unforeseen that will be discovered that will be most important.

My personal view about this is that we should lose no opportunity to prosecute this research in competent hands, and also that we lose no opportunity to see to it that those who are attracted and have

ability along the lines of this type of research are persuaded to go into it. Research cannot be done without competent people, and we should therefore see to it that we train these competent people. Only by the systematic study in competent hands will we really reach a good conclusion. In the meantime it seems to me that today's hearings and the other hearings which have been held are pretty convincing testimony that by the interest and thoroughness with which this committee has approached these problems and by the competence and thoroughness with which the Atomic Energy Commission and the Institutes of Health and others have been working along these lines, we have every reason to believe that we are on the right track. If anything else is needed—and I think it is—we have the two committees that have been mentioned—the National Committee for Protection Against Radiation and the committee of the National Academy of Sciences that can be counted upon to monitor this from the standpoint of desirable standards of tolerance levels, and so on, and also from the standpoint of review of the research which is going on. If that is done, and continued actively, it seems to me that we have the situation as well in hand as we could possibly hope.

Senator ANDERSON. Thank you very much. Are there any questions?

Chairman DURHAM. I have one statement. I do not believe I ever heard a finer summary of the whole problem in so few words.

Dr. WATERMAN. Thank you.

Representative COLE. I was going to say exactly the same thing, except I may have used different words. I think it is most appropriate, Doctor, that you are the last witness. I am not sure but it presently appears you are the last witness to make this résumé, and a synopsis of the subject matter that is of concern to this committee and the cause of the hearing. Like Mr. Durham, I compliment you on your capacity to pierce through the maze of all this information that has been given and heard in the last 2 weeks and lay out in the ledger for us and the public to evaluate the different factors that are to be taken into consideration in striking a balance on this problem.

Dr. WATERMAN. Thank you, sir.

Senator ANDERSON. Thank you very, very much, Dr. Waterman.

Dr. Alexander, do you have any short comment you wish to make before we are thraugh with this hearing?

Dr. ALEXANDER. I might say a few words on the part of the Department of Agriculture.

Senator ANDERSON. We certainly do not want that Department left out, we assure you.

Dr. ALEXANDER. I thought you would not. I always feel that Senator Anderson has an interest in the Department of Agriculture from some years back.

The program of the Soil Conservation Service of the Department of Agriculture is entirely one of support to the fallout program that has been presented here. We collect samples, select areas of work and help in interpretation of results in relation to food supplies for man and animals.

The Agricultural Research Service carries out basic research that contributes to our understanding of the behavior of fallout in soils, plants, and animals. We in the Department of Agriculture are glad to be a part of this program.

I might say for Mr. Cole and Mr. Anderson that my grandchildren are drinking copious quantities of milk, and I have no fear whatever for their future from the standpoint of the hazard of strontium 90.

Senator ANDERSON. From the size of you, you have drunk some yourself.

May we find out if either of the representatives of the Department of Defense have a word as we close?

Dr. SHELTON. I have no formal statement for you, but I do want to say a few words in order that the committee be informed of the fallout research being conducted in the Department of Defense, and principally in the Armed Forces special weapons project, a name which has occurred repeatedly in testimony to you.

I would like to repeat very briefly the pertinent portions of some of that effort.

In regard to Dr. Dunham's statements to you concerning the AEC research program in fallout and effects on man, several of the programs mentioned are jointly funded by the AEC and DOD. Dr. Dunham's organization and the organization which I represent work rather closely together on these common problems.

Representative COLE. At that point, Dr. Dunham indicated the total as I recall of $30 million. Does that indicate that the AEC's portion is $30 million, or does that $30 million include defense appropriations?

Dr. SHELTON. When we jointly fund a program, I would imagine he would include his contribution to that program and probably not include our contribution in the amount he has given.

Representative COLE. Are you going to tell us what your figure is?

Dr. SHELTON. I will indicate roughly those numbers; yes, sir. I wanted to indicate to you that the Department of Defense participation in documenting fallout and its effects on man are of a research nature, and we do have a broad interest. The AFSWP research directly related to fallout and its effects on man can be conveniently divided into three rather distinct areas. The first area in which the Department of Defense through the Armed Forces special weapons project has participated has been the documentation of fallout on the weapons test series. This activity has been principally concerned with the local fallout. Considerable effort has been expended and is now being expended in analyzing and reducing the data obtained to date. We anticipate our main effort in future will be along these lines.

It must be realized that millions of dollars and an extremely large effort has been expended in documenting fallout in order that from the standpoint of the Department of Defense the weapons can be properly employed, if necessary. We are not really complacent, however, regarding local fallout.

Senator ANDERSON. I saw you jump across a couple of pages.

(Discussion off the record.)

Dr. SHELTON. I do have a few more statements to make.

We are not complacent in the Department of Defense regarding local fallout and hence we are not complacent about that portion which is left over, which will manifest itself in the latitudinal and the worldwide fallout. As new weapons and brust conditions arise, we will certainly document those, as well as appears feasible.

There is a second large area in which we are participating and that is because of the importance of the worldwide fallout. The Depart-

ment of Defense does have a stratospheric program. The Department of Defense program has been coordinated with a similar project in the AEC. The Department of Defense will continue research on worldwide sampling and we do utilize the private organizations for analysis of those samples.

There is a final and third large area of research in the Department of Defense, and that concerns the laboratory programs on the effects of ionizing radiation on man. Lieutenant Colonel Hartgering of Walter Reed gave you the results of the uptake of various isotopes in man during testing.

Chairman DURHAM. How much of your work is classified and how much is declassified?

Dr. SHELTON. That changes from time to time. During a test series the work under progress at that time may be classified. Indeed, the subject just mentioned as performed by Colonel Hartgering is an example; we did not know during the periods of taking those samples on the Nevada operation, and finally the Pacific operation, just what would turn up. We did not want to reveal the number of shots. So that was classified. It was classified at one time, and we reviewed that subject and we were happy to present those results to you and they were unclassified. What is classified today may not be classified tomorrow.

Chairman DURHAM. I am speaking primarily of radiation and fallout.

Dr. SHELTON. Details of the fallout from a specific shot of a specific yield, having a specific burst condition, has been treated in a classified manner. It reveals specific information on that particular event. The AEC and we have periodically released fallout patterns of a generalized nature to indicate the areas and hazards involved. So we do the best we can in getting out as much information in an unclassified manner. We use classified information to develop the unclassified.

Representative VAN ZANDT. Dr. Shelton, how long does it generally take you to complete your study and then release to the public nonclassified information?

Dr. SHELTON. If something is of a startling nature, such as the obvious very large fallout patterns being involved with thermonuclear weapons, such as the March 1954 shot; we released the fallout patterns from that within a period of 4 to 5 or 6 weeks following the event. It was put in the best way we knew how not to divulge specifically the weapon, but to provide the necessary information to the people, and that came out jointly by the AEC and Department of Defense.

Representative VAN ZANDT. In other words, it takes about 4 or 5 or 6 weeks for you to delete the classified material from the information which you receive after a test.

Dr. SHELTON. Typically for us to really understand what we have and to put it out out and not have to retract and change it. We have consolidated a position of accuracy of the data by then.

We are continuing the human measurement program at Walter Reed, and we are extending that to other lines of approach. Dr. Langham mentioned the LASL whole body counter. We anticipate using a whole body counter in the Department of Defense. We would have available to us a large group of people whom we know where they

have been stationed, and where they will be stationed in the future. We will be checking some personnel and we hope to make a contribution in that area.

Concerning the effects of strontium 90 on man, we are jointly funding with the AEC two sizeable projects, one being the strontium 90 programs on dogs, and we have another one with them at Oak Ridge. At the present time we are spending in these two projects and others something over a quarter of a million dollars annually on research directly related to the biological effects of fallout on man. None of our medical programs are classified. That is, the results come right out as they are produced at those individual places.

So I have covered, then, the three broad areas in which the Department of Defense continually and has in the past expended quite an effort. We are well aware of the problems and we are making our contribution to solving the problems.

Senator ANDERSON. Thank you very much. I am privileged to check some of the work in one of the areas where the special weapons project is interested. It is a very active operation. I know how much you have done, and I want to compliment you on it.

This brings to a close the first part of these hearings. I do hope as a result of these hearings the various agencies which have testified, the various groups that have been represented, the scientific fraternity generally, will examine these hearings and give the committee such guidance as they may be able to for any subsequent hearings we may have.

We are going to regard these as adjourned, merely until additional material may be obtained and the committee, I am sure—and I am speaking for the chairman of the committee as well as the chairman of the subcommittee—thank all the witnesses very sincerely for their fine contributions.

Chairman DURHAM. I want to thank the scientific profession for the excellent hearings we have had. It is something that will be valuable for the future and to the country at large.

Senator ANDERSON. Thank you all.

(Thereupon at 4 p. m., Friday, June 7, 1957, the hearings were adjourned.)

APPENDIX 1

PRINCIPAL TECHNICAL SPEECHES AND PAPERS ON FALLOUT BY COMMISSIONER W. F. LIBBY

[Reprinted from Science, v. 122, July 8, 1955: 57–58]

DOSAGES FROM NATURAL RADIOACTIVITY AND COSMIC RAYS

W. F. Libby [1]

The radiation dosages that people receive from the natural radioactivities and cosmic rays have been calculated and are given in Tables 1, 2, 3, and 4. Some direct observations are given in Table 5.

Table 1 gives the dosages in milliroentgens per year for exposures at various altitudes directly over ordinary granite, typical sedimentary rock, and open oceans. Surface dosages decrease with height above the ground because of air absorption; 50-percent reduction occurs for every 370 ft.[2] For comparison purposes, it is interesting to note that in the United States, the average exposure *rate* from total fallout from atomic tests on 1 Jan. 1955, was about 1 mr/yr.[3] The total dose during 1954 probably averaged about 15 mr,[3] principally because of the Pacific tests in the spring.

The values listed in Table 1 were calculated on the following basis. The roentgen was taken to be 100 ergs of energy per gram of water. (Actually this definition is that of the rad, the internationally recognized unit of radiation dosage. For gamma rays it is nearly equal to the roentgen, which is 93 ergs/g.) The absorption coefficients of all radiations in tissue were taken as being equivalent to those of water. The dosages from the natural radioactivities in the earth were calculated on the approximation that the energy absorbed per gram by the human body on the surface of the earth is, to a sufficient approximation, equivalent to that absorbed per gram by the top layers of the rock of the earth's surface itself from the gamma radiation emitted by the rock.[4] In other words, the total gamma-ray energy produced in a gram of granite from the thorium, uranium, and potassium contained was taken to be equal to the energy absorbed per gram of human tissue in the human body on the surface, except that a factor of 2 was used to correct for the geometric loss. It was interesting to observe that this simple method of calculation gave results in good agreement with those based both on separate consideration of each of the complicated radiations emitted by thorium and uranium in the rocks and on the use of the individual absorption coefficients for these radiations in tissue, together with correction for the "buildup" factors as the radiation is scattered and diffuses out of the rock.[5]

The abundance of uranium, thorium, and potassium in granite were taken as 4×10^{-6} g/g (*1*), 13×10^{-6} g/g (*1*), and 0.03 g/g, respectively (*1*). In selecting these numbers, it was realized that these were only averages and that fluctuations around these values do occur, that uranium contents as high as 200 ppm have been found in granite, and that thorium has been found as abundant as 500 ppm in some granites.

For sedimentary rocks, the general average figure of one-fourth of the values quoted for granites has been used. It is realized, however, that this is very approximate, because the amounts of the various radioactive minerals in the sedimentaries fluctuate widely. The abundances of uranium and potassium in sea water were taken, respectively, as 1.3×10^{-9}g/g[1] and 3.5×10^{-4}g/g[1]. The abundance of potassium in the human body was taken as 2×10^{-3}g/g,[6] and the abundance of carbon in the human body was taken as 18 percent. For the calculation of the dosage from radium assimilated in drinking waters throughout the normal lifetime, the bone weight was taken as 10 percent for the adult man. But for relatively brief periods of assimilation when the radium would be expected to be concentrated in the small volumes of the bone most metabolically active, the figure of 1 percent was used. All these numbers of the human body were taken as being equivalent to those of the "standard man".[7]

The dosages resulting from cosmic radiation were calculated from the ionization chamber data of Millikan et al.[8] From these data the dosages were calculated at altitudes up to 20,000 ft. and at the latitude of 55° N (geomagnetic) as well as at the geomagnetic equator. The results are given in Table 2. It should be mentioned that the biological effects per unit energy may be larger for cosmic radiation, because it consists of high-energy particles rather than gamma radiation.

The natural radioactivity in the human body contributes the dosages given in Table 3. Of the 19-mr/yr dosage from potassium, 17 mr/yr is from the beta rays of the potassium itself. These were taken to be of a mean energy 40 percent of the maximum energy of 1.36 Mev. The specific activity of natural potassium was taken as 1800 beta rays per gram, per minute and 180 gamma rays of 1.45-Mev energy per gram, per minute.[9] The gamma rays that contribute the remaining two units of the dosage of potassium were calculated on the basis of the assumption that only half of the gamma-ray energy is actually absorbed in the body. This leads to the result that in a packed crowd the radioactivity from the potassium in one's neighbors' bodies contributes an additional dosage of 2 mr/yr.

TABLE 1.—*Total radiation dosages from normal background radiation (mr/yr)*

Altitude of ground surface (feet)	Ordinary granite		Typical sedimentary rock		Open ocean	
	Equator	55° N	Equator	55° N	Equator	55° N
Sea level	143	147	76	80	53	57
5,000	150	170	83	103	----------	----------
10,000	190	230	123	163	----------	----------
15,000	270	350	203	283	----------	----------
20,000	414	560	347	493	----------	----------

The dosage from carbon was calculated on the basis of the assumptions that the body is 18-percent carbon; the specific radioactivity of carbon is 15 disintegrations/g, per minute;[10] and that the mean energy of the beta radiation is 40 percent of the maximum energy of 167 kev.[9]

In Table 4, various ordinary but somewhat unusual circumstances are used to illustrate the types of exposure that can occur in normal living. A wristwatch worn 24 hr/day that has a luminous dial assumed to have 1 μc of radium per watch—a figure perhaps slightly larger than the average—would give the central body, including the sex organs, a dosage of about 40 mr/yr. An airplane pilot flying 24 hr/day with an instrument panel consisting of 100 dials with 3 μc of radium each would receive, at an average distance of 1 yd, a dosage of 1300 mr/yer.

In order to check whether the dosages calculated here and given in Tables 1 to 4 are essentially correct, some direct measurements reported by various

observers are given in Table 5. They agree reasonably well with the external component of the total dosages given for sea level in Table I—the residues after subtracting 20.5 mr/yr, the dosage from body radioactivities given in Table 3.

It is interesting that the variations in natural dosage are large and under certain conditions the natural dosage may be nearly 100 times higher than the minimum—the dosage of seafarers. The fallout dosage rate in the United States on 1 Jan. 1955—1 mr/yr—was only 2 percent of this lowest natural dosage rate. Of course, during a test period when bombs are fired, the fallout dosage rates may approach, or somewhat exceed, the natural dosage rate for a few days before decay and weathering processes reduce them in a few weeks to rates that are small percentages of the natural background.

TABLE 2.—*Cosmic ray dosages*

Altitude (ft.):	*Dosages (mr/yr)*
Sea level	33 to 37
5,000	40 to 60
10,000	80 to 120
15,000	160 to 240
20,000	300 to 450

RADIOACTIVE FALLOUT AND RADIOACTIVE STRONTIUM

W. F. Libby[1]

The radioactivity that falls out of the atmosphere after the explosion of a nuclear weapon is called the radioactive fallout. In the ordinary atomic bomb, for example, for each 20,000 tons of TNT equivalent of explosive energy, about 2 pounds of radioactive materials are produced. In these 2 pounds are some 90 different radioactive species varying in lifetime from a fraction of a second to many years. This mixture of radioactivity decreases in radioactivity in such a way that for every sevenfold increase in age, the total radioactivity is decreased tenfold. Thus the radioactivity by 7 hours after the explosion has decreased to one-tenth the radioactivity of 1 hour, and in 49 hours to 1/100, in 2 weeks to 1/1000, in 3 months to 1/10,000, and so forth.

The conditions of fallout are largely determined by the amount and type of material vaporized into the fireball of the bomb itself. A bomb fired in the air contributes such a relatively small amount of matter to the cloud that the particles formed after dissipation of the enormous energy released are of necessity very tiny and therefore very slow in settling. The result is that most of the radioactivities are expended in the air and the area over which the fallout occurs is rendered very large indeed, extending to the ends of the earth in minute although detectable amounts.

A bomb fired on the surface of the earth, however, may have an appreciable portion of its radioactivity reprecipitated within relatively short distances, while bombs fired beneath the surface of the earth may place essentially no fallout radioactivity in the atmosphere. Therefore, the question of the area of contamination to be expected from nuclear weapons cannot be answered categorically without specifying the degree of contact of the fireball with the surface of the earth and probably also specifying the characteristics of this surface. Obviously water would differ considerably from soil in its ability to precipitate radioactive fallout. The coral in the southern Pacific islands that are used for the larger United States weapons tests will under the great heat decompose to form calcium oxide, which will then rehydrate to form calcium hydroxide, which in turn will absorb carbon dioxide to form a crust of calcium carbonate. Obviously such a complicated series of chemical reactions will make the fallout particles from the great tests at Eniwetok differ from what would be observed if

[1] The author is a member of the U. S. Atomic Energy Commission.

the same weapons had been fired over ordinary sand or granite. We cannot imagine all of the details in which the nature of the soil will affect the local fallout, but it is clear that the effects will be substantial.

In the weapon test operations, great care is taken to insure that no danger results from fallout. Criteria are used that are meant to insure that this is so. However, it is well to note that it is from the test operations that we have learned what we do know about the problem of civilian defense against fallout. We must speak of test experience, for it is the only source of experimental information about the phenomena of radioactive fallout.

The radioactivities resulting from the burst of a nuclear weapon can be classified as follows: (i) radioactivities induced in the environment and (ii) products dependent directly on the nature of the weapon. The environment can be made radioactive only by neutrons, but all nuclear weapons involve large numbers of neutrons, some of which are certain to escape into the surroundings.

RADIOACTIVITIES INDUCED IN THE ENVIRONMENT

Taking air bursts first, our problem is: What do neutrons do to air? The answer is simple. They make radioactive carbon, C^{14} which has a half-life of 5600 years. Fortunately, this radioactivity is essentially safe because of its long lifetime and the enormous amount of diluting carbon dioxide in the atmosphere. The cosmic rays themselves make neutrons, which, of course, make radiocarbon. In fact, the earth has on its surface a total of 80 tons of radiocarbon from the cosmic radiation. Now, since each neutron forms one C^{14} atom of mass 14 times the neutron's mass, this corresponds to 5.2 tons of neutrons, and we see that this enormous number of neutrons would have to be produced and escape in order that nuclear weapons would just double the feeble natural radioactivity of living matter due to radiocarbon. Such an increase would have no significance from the standpoint of health. The atmosphere itself contains only 1.5 percent of the total carbon with which the cosmic-ray-produced radiocarbon is mixed, the main part being dissolved in the sea, so we expect that nuclear weapons could produce a short-range rise in the radiocarbon content of the carbon dioxide in the atmosphere, which later would decrease as the atmospheric carbon dioxide mixed with the sea. Therefore, only 1.5 percent as many neutrons would be required to double the natural radiocarbon content of atmospheric carbon dioxide for this time before mixing with the sea could occur, or about 78 kilograms or 170 pounds of neutrons. To orient ourselves, the 20,000-tons-of-TNT-equivalent atomic weapon involves the fission of 1 kilogram of uranium or plutonium and the liberation of about 10 grams of neutrons. If all these neutrons escaped into the atmosphere, it would obviously require 7800 such weapons to double the radiocarbon content of the atmospheric carbon dioxide even with no mixing with the sea, and about 520,000 with complete mixing. These correspond to explosive energies of 156 and 10,400 megatons of TNT, respectively, if all neutrons formed escaped. A reasonable escape figure might be 15 percent, so we can expect that nearly 1000 megatons of fission would be necessary just to double the atmospheric radiocarbon content, and that about 66,000 megatons would be necessary for the same effect on a long-term basis.

The interchange between the atmosphere and the sea water, which is constantly taking place, would deplete and remove the excess radioactive carbon dioxide. Now it is known from measurements of the radioactive hydrogen, tritium—which is also made in the atmosphere by the cosmic rays—that this interchange is slow. In fact, we learn that the radioactive water is formed by the burning of the tritium made by the cosmic rays is not diluted by more than the top 100 meters or so of sea water in its lifetime of about 18 years. The carbon dioxide dissolved in the water is about equal to the total in the air. In other words, a dilution by more than the twofold that corresponds to the dissolved carbon dioxide in the top 100 meters of ocean water would take longer than 18 years. However, the dilution by this factor of 2 would occur essentially immediately within a matter of weeks or months. Therefore, we would have to double our estimates for even the short time scale activation of the atmosphere to reach the enormous figure of 2000 megatons of fission required. Thermonuclear weapons, of course, also involve neutrons. For a given energy release, they produce somewhat more neutrons than fission weapons; however, the order of magnitude of atmospheric activation would not be greatly different. So our estimates apply to all nuclear weapons. The essential point is that the atmosphere is difficult to activate and the activities produced are safe. In addition to

carbon-14, there are a few others produced in low yield; they include tritium and very short-lived products, but none is produced in sufficient amounts to be hazardous.

For weapons fired on the surface, the activation of the surface materials is a possibility, but in general it appears that most of the neutrons form stable isotopes and that the amount of radioactivity produced, at least with ordinary surface materials, is relatively small. The principal radioactivities produced by nuclear weapons are produced in the weapons themselves, and not in the environment.

RADIOACTIVITIES PRODUCED IN WEAPONS

Turning now to the radioactivities naturally produced in nuclear weapons themselves, probably the most important is radioactive strontium, which has a half-life of 28 years. The first reason this is so important is that strontium is chemically similar to calcium, which is one of the main mineral constituents of the body. Bone consists principally of calcium phosphate, and for this reason radiostrontium, like calcium, is deposited in the bone. The amounts of ordinary nonradioactive strontium naturally present are so small that the radioactive strontium will follow ordinary calcium into the body. The second reason that radioactive strontium, Sr^{90}, is an important fallout radioactivity is that it has a long but finite lifetime—28 years half-life, 40 years average life—and thus has a persistent effect. Third, because of its bone seeking property, it stays in the body a long time. Fourth, the probabilities of body ingestion can be high. Finally, the fifth reason for its importance is that strontium-90 is produced in high yield in the fission reaction—about 4 or 5 percent of all fissioning atoms yield this isotope.

In order to orient ourselves about this, let us consider the maximum permissible concentration recommended by the National Committee on Radiation Protection for AEC workers for radiostrontium—1 microcurie for the standard man, whose body is taken to contain 1000 grams of calcium in total. The maximum permissible concentration is of course well below any level at which one would expect any damaging effects to appear. On the basis of experiments with animals, statistically observable increases in the number of bone tumors *should not* be expected to appear at *less than* 10 times this level.. As we go above this figure, the chance for bone tumors occurring increases rapidly so that the likelihood of bone cancer with 30 to 40 times that figure is appreciable.

INTAKE OF STRONTIUM-90

Let us consider in some detail the mechanism by which this most important fallout radioactivity produced in nuclear weapons might be expected to enter the human body. The first point is that from the point of view of fallout there are essentially two classes of nuclear weapons—the high-yield megaton weapons and the lower-yield kiloton weapons. All nuclear weapons produce atomic clouds that rise to heights dependent on the energy released, and the clouds from the megaton class of weapons rise rapidly up through the tropopause and pass into the top layer of the atmosphere, which we know as the stratosphere. This part of the atmosphere is essentially isolated from the lower layer in which we live, the troposphere, and where all of our normal winds, storms, and so forth, occur. Therefore, radioactivity produced in megaton weapons is placed largely immediately in the stratosphere, while the smaller kiloton weapons produce clouds that in general do not reach into the stratosphere, but stop near the tropopause—the imaginary boundary between the stratosphere and troposphere—and have the bulk of their radioactivity left in the troposphere.

In the troposphere where rain occurs, any particulate matter will be washed down in a period of days or weeks. It is easy to show, for example, that 0.1 inch of ordinary rainfall will probably remove essentially completely all particulate matter except for that which is so small as to be almost of molecular dimensions. In other words, for 0.1 inch of rainfall one can be quite certain that the air between the layer in which the rain originates and the ground is washed clean of fallout activity, except for the minute fraction that may be so small that it moves with the air out of the way of the falling raindrops as they make their way toward the earth; and even this tiniest fallout material is likely to be precipitated also, for it will migrate rapidly by molecular-type motion and in this manner is likely to absorb itself on other particulate material and so be rained out. For these reasons, tropospheric radioactive fallout does not stay in the atmosphere for more

than a matter of weeks. It may make two or three trips around the earth in a given latitude before being entirely removed, but its lifetime in the atmosphere will be a matter of weeks.

This is in very sharp contrast to the material that is placed in the stratosphere by megaton weapons; this material appears to stay there for a matter of years. Perhaps 10 years is a good average, at least for the weapons fired to date. It is well to bear in mind that this conclusion may be dependent on the nature of the material carried up in the cloud, but our present experience indicates that the fallout from megaton weapons that does not occur essentially in the first few hours or days, and is therefore deposited mainly locally, is deposited only at a very slow rate corresponding to an average time in the stratosphere of about 10 years. As a result of this long residence time in the highest layers of the atmosphere, the winds mix and distribute the radioactive material broadly over the earth and one finds, when the fallout does finally find its way down into the troposphere where the rain and snow wash it out, that the rates of recipitation are relatively uniform over the entire earth's surface.

Returning now to radiostrontium—at the rate of 1 kilogram of fission for 20 kilotons of TNT equivalent, 2 megatons of fission energy would be equivalent to very nearly 1 millicurie of strontium-90 per square mile of the earth's surface, or about 79 disintegrations per minute, per square foot of the earth's surface. The average soil of the earth has about 20 grams of calcium that is in a form available for plant metabolism in the top 2.5 inches for each square foot of area. Now, recalling the maximum permissible concentration level of 1 microcurie per standard man and noting, as will be shown later, that in order that this concentration not be exceeded, the topsoil of the earth should not contain any more radiostrontium than would correspond to 10 times the concentration in the human body that is just permissible—that is, 1 microcurie per 1000 grams of calcium, or 2200 disintegrations per minute, per gram of calcium—we find that 11,000 megatons of fission energy would produce this average level of radioactivity. Actually, as I will indicate, there can be a concentration of strontium-90 in the soil about 10 times greater than the recommended maximum permissible concentration before one would expect a man living in such an environment to accumulate a maximum permission concentration. The afore-mentioned 11,000 megatons of fission energy would yield a strontium-90 content in human beings just equal to the maximum permissible concentration (MPC); at less than 10 times this value, or below 110,000 megatons energy equivalent, statistically observable incidence of bone tumor should not appear; but at 30 to 40 times the MPC, or 330,000 to 440,000 megatons, the likelihood of untoward effects would be appreciable. Even the lowest of these figures is very far in excess of the total energy released to date.

KINDS OF FALLOUT

High-yield weapons fired near the surface have a portion of their activity deposited in and on particles large enough to fall out in the first few hours or days. Thus we have three kinds of fallout from high-yield weapons.

1) The first, or local, is due mainly to large-sized particles. This may cover a considerable area depending mainly on winds. In the 15 February 1955 release of the Atomic Energy Commission that described the experience in the Marshall Islands in the Castle test series in the spring of 1954, some 7000 square miles were described as being contaminated by this type of fallout.

2) The second fallout from the high-yield weapons is that portion which resides on the small particles, but which never reaches the stratosphere and thus stays in the troposphere until it is carried down by rainfall or settles out. There is thus a band of fallout in the same general latitude as the test site; the material may circle the earth two or three times before it is precipitated, but it does fall out within the first few weeks.

3) However, a large part—half or more depending on firing conditions—of the radioactive yield from high-yield weapons resides in the third category, which is the fallout that occurs from the stratosphere itself. Of course, some of the large local fallout may form particles which were lifted into the stratosphere, but which were so large and so bulky that they fell out rapidly anyhow. The finely divided material that reaches the stratosphere apparently stays there for years in the main. A slow leakage through the tropopause into the troposphere occurs—apparently something like 10 percent per year descends. Measurements of the strontium-90 content of soils, rain and snow, and biological materials on a worldwide basis have all shown that strontium-90 fallout occurs all over the

world at rates that are not very dissimilar from one another, except that there is a tendency in the middle latitudes in which the tests are conducted for an extra fallout, presumably of the aforementioned tropospheric variety. Since the completion of the Castle series of tests two years ago, this worldwide rate of fallout has approximated 1.5 millicuries of radiostrontium per square mile, per year. We thus see that radioactive fallout from the stratosphere is a very slow process. This is very fortunate indeed, since the high-yield weapons thus have a major part of their radioactivity dissipated in the atmosphere in a harmless way if they are fired in the air or on the surface.

The fallout apparently occurs in the final step by a washing down of the tropospheric air by rain together with direct falling. The radiostrontium descends from the stratosphere into the troposphere by the processes of diffusion and falling, and is then caught up by the tropospheric weather and in a matter of a few days is deposited. Reasonable estimates for the middle latitudes indicate that the average life in the troposphere is about 1 week.

DEPOSITION OF STRONTIUM-90

The radiostrontium comes down mainly in raindrops although fine morning mists and fogs may be particularly effective in this regard also, as well as surface contact and direct falling. It descends on the foliage and on the soil. That fraction of it which falls on plant leaves has a good chance of being absorbed directly into the plant—much in the way that most modern leaf fertilizers operate. The Eniwetok tests were conducted on coral islands and as a result their fallout may be largely water-soluble. In any case, direct measurements of the radiostrontium content of alfalfa and other crops showed them to be appreciably higher in radioactivity than the soils on which they grew, strongly indicating that a leaf assimilation mechanism is important. The rain falls and carries radioactivity, but when it runs off to the rivers and the seas it is nearly pure because of the action of the soil in absorbing the fallout, so that rivers are essentially free from radiostrontium. Lakes and reservoirs have a content that corresponds approximately to their surface areas only. The radiostrontium is absorbed in the top 2 or 3 inches of soil and held there very tenaciously. Plowing, of course, buries it more deeply, but it appears that in unplowed soil the radiostrontium does not move in a matter of 2 or 3 years.

The researches on radiostrontium conducted by the Atomic Energy Commission have been extensive. The AEC has sampled soils on a world-wide basis and submitted the samples for analysis of radiostrontium content to the Health and Safety Laboratory of the New York Operations Office of the Atomic Energy Commission, the Lamont Geological Observatory of Columbia University, and the Enrico Fermi Institute for Nuclear Studies at the University of Chicago. Direct fallout collected on gummed papers, milk and cheese, alfalfa, animal meat and bone, and even human bodies has been extensively studied. On the basis of the information so obtained, it is possible to say unequivocally that nuclear weapons tests as carried out at the present time do not constitute a health hazard to the human population insofar as radiostrontium is concerned, and it is believed with good reason that radiostrontium is likely to be the most important of the radioactivities produced. It is well to note that since radiostrontium is assimilated in the bones it constitutes essentially no genetic hazard, for its radiations do not reach the reproductive organs.

The milk and cheese radiostrontium content is not as high, relative to that of the grass which the cows eat, as one might expect. There appears to be a discrimination against the fallout material such that the calcium in milk and cheese is roughly one-fifth to one-tenth as radioactive with radiostrontium as the grass that the animals eat. There are various possible physiological explanations of this, and the conclusion itself may not be completely certain, but the data available to date indicate this to be true. In addition, the plant uptake of radiostrontium from soil does discriminate somewhat against radiostrontium as compared with calcium. The calcium taken up from the soil into the plant has in general about one-half the radiostrontium content that the soil calcium has. These two results protect the human population against ingestion of radiostrontium, since milk and cheese are the principal sources of calcium in the human diet. We find, therefore, that the radiostrontium content of human bodies is the lowest of all animals measured and is lower than the average soil and the average foliage by tenfold. The Sr^{90}-to-calcium ratio in young people—

whose bones are still forming—corresponds to about 1/1000 of the maximum permissible concentration recommended for adults—1 microcurie per standard man containing 1000 grams of calcium. The average soil in the United States contains about 10 times more, whereas abroad the radiostrontium content in other areas of the world not subject to the local test fallout is about one-third of that for the United States.

The surface air itself contains radiostrontium due to the fallout from the stratosphere and corresponding to the average time between rainstorms in which it can collect. Filtration of air at sea level discloses radiostrontium on filters if the filters are fine enough, even in periods when bombs are not being tested; thus the only fallout is from the stratosphere reservoir from the high-yield weapons. Measurements in the antarctic on snow samples collected there show that the fallout rate in January and February 1955 was comparable with that observed in the middle latitudes.

CONCLUSION

Finally, although the main part of the radioactivity from high-yield weapons fortunately dissipates in the stratosphere, the small but very significant part that falls out within a few hundred miles of the site of the explosion for weapons fired on the surface constitutes a very real hazard and nothing I have said should be interpreted otherwise. The weapons tests are conducted with great attention to this and the other dangers and every effort made to protect against misadventure. What we have learned from the studies I have described—which by the way have been conducted under the name Project Sunshine—is that these local precautions should be entirely adequate and the worldwide health hazards from the present rate of testing are insignificant.

RADIOACTIVE STRONTIUM FALLOUT

BY DR. W. F. LIBBY

COMMISSIONER, UNITED STATES ATOMIC ENERGY COMMISSION

Communicated May 2, 1956

CONVERSION FACTORS

"Average soil"	= 20 gm Ca/ft^2 in top 2.5 inches
1 MPC unit in any medium	= 1 μc Sr^{90}/kg Ca
	= 2,200 dpm Sr^{90}/gm Ca
1 megaton fission distributed uniformly over entire earth	= 0.0009 MPC unit
	= 0.5 mc Sr^{90}/mi^2

I. EXPERIMENTAL MEASUREMENTS

Strontium 90 is of particular importance among the fission products because of chemical and physical characteristics which result in comparatively high retention in the skeleton. These are chemical similarity to Ca, an element essential to both plants and animals; an average life of about 40 years; and a low rate of elimination from the skeleton. On the basis of studies of the comparative effects of Sr^{90} and Ra^{226} in experimental animals and of the effects of Ra in humans, the generally accepted maximum permissible body burden (skeletal content) of Sr^{90} in adult humans is 1 microcurie. Since the body of the average adult contains about 1,000 gm. of Ca, this is equivalent to saying that the maximum permissible average concentration of Sr^{90} in the adult skeleton is 1 μc/1,000 gm. of Ca. For purposes

of this discussion, this ratio of Sr^{90} to Ca, in whatever medium it may occur, is designated an "MPC unit." One MPC unit of Sr^{90} in the human body is considered to be safe—a significant risk occurring only at much higher dosages.[1] The majority of analyses for Sr^{90} encountered in this work were of the order of a few thousandths of 1 MPC unit. For purposes of orientation, it is helpful to remember that 0.001 MPC unit corresponds to 1/1,000 μc of Sr^{90}/kg of Ca, or 2.2 dpm of Sr^{90}/gm of Ca. The small weights of Sr^{90} involved in both the radiostrontium and normal strontium being considered, and the similarities of the element to Ca, justify the assumption that its distribution in the body will follow that of Ca in a general way.

Two megatons of fission will produce 1 millicurie (mc.) of Sr^{90}/mi², if the fission products are uniformly distributed over the earth's surface. If this amount of radioactivity is mixed with the available Ca in the soil, an average of about 20 gm/ft² in the top 2.5 inches of soil, the specific radioactivity produced is 0.0018 MPC unit. It is observed that most of the Sr^{90} fallout is concentrated in the top 1 or 2 inches of soil. For example, in Tables 1 and 2, which show the Sr^{90} burden in the fall of 1953 in the soil of twelve farms in the Wisconsin-Illinois area as well as in the alfalfa and the milk of the cows fed thereon, we note that the top inch of soil contains about 56 per cent and the next 5 inches contain the remaining 44 per cent of the total Sr^{90}. Recently some evidence has been discovered that the radiostrontium finds its way to greater depths.[2] In Table 2 data are given for Iowa soil collected in 1937 which, as expected, shows no Sr^{90}. The average available Ca content of the domestic soils was 8 ± 1 gm Ca/ft²/in., the average fraction of total Ca exchangeable was 68 ± 3 per cent, and the average Sr^{90} content was 4.7 ± 0.4 mc/mi².

* E. A. Martell and W. F. Libby, Project Sunshine Bull. No. 10, January 10, 1955; E. A. Martell, *ibid.*, Suppl. 3, September 1, 1955.
† Samples collected by Dr. Lyle T. Alexander, Chief, Soil Survey Laboratory, Plant Industry Station, Beltsville, Maryland.

As might be expected because of the similarity of the Sr chemistry to that of Ca, milk and cheese show radiostrontium without exception. Figures 1*a*, 1*b*, 1*c*, and 1*d* show the data for both foreign and domestic samples.

Average Ca content (exchangeable): 8.0 ± 1 gm Ca/ft²/in = 8.6 ± 1 mg Ca/cm²/in.

Average fraction of total Ca exchangeable = 68 ± 3 per cent (assuming 6 N HCl to extract all Ca).

$$\frac{Sr^{90}\text{ concentration, 1–6 inches}}{Sr^{90}\text{ concentration, 0–1 inches}} = 0.23 \pm 0.027.$$

Effective depth at top 1 inch concentration = 2.15 inches = 19 mg Ca/cm² = 18 gm Ca/ft².

Pre-atomic samples:

Location	Lab. No.	Date Sample Taken	Depth of Sample (Inches)	
Iowa, Carrington loam	C-2916	1937	0–3	0 ± 0.00005 MPC units
Iowa, Carrington loam	C-2917	1937	3–13	0 ± 0.00005 MPC units

* All radiostrontium measurements made in Chicago Sunshine Laboratory (see E. A. Martell and W. F. Libby, Project Sunshine Bull. No. 10, January 10, 1955; E. A. Martell, *ibid* Suppl. 1, March 1, 1955; Suppl. 2, June 1, 1955; Suppl. 3, September 1, 1955; and E. A. Martell. Project Sunshine Bulletin 11, December 1, 1955).

The amount of radiostrontium found in humans is shown in Figures 2*a* and 2*b*. The data show that the present Sr^{90} content probably averages somewhat less than 0.001 MPC unit in young people. Apparently a number of barriers protect the human skeleton from this fallout radioactivity.

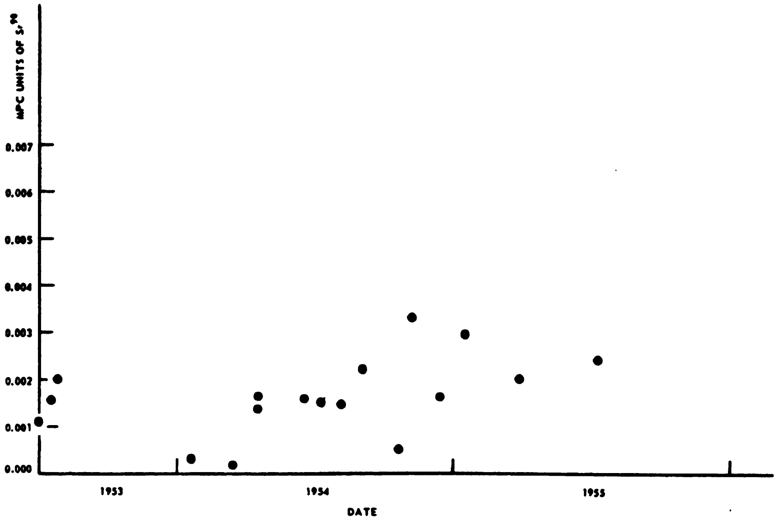

Fig. 1*a*.—Wisconsin cheese—Sr^{90} content

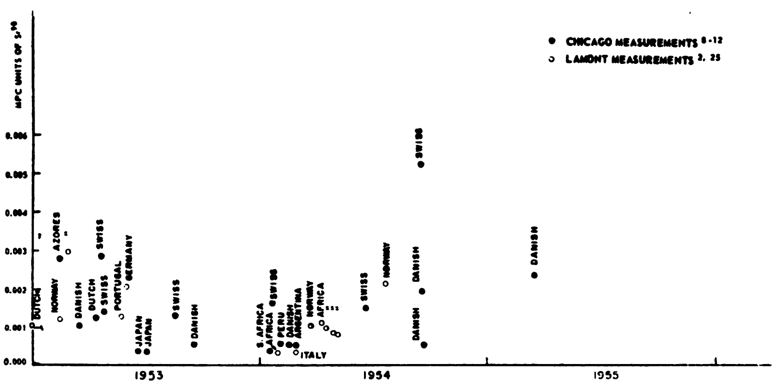

Fig. 1*b*.—Foreign cheese—Sr^{90} content

Measurements have been made on animals, principally cattle and sheep. These data are given in Figures 3*a* and 3*b*. We see here that the contents are much higher than those for milk and human samples, apparently due to selective deposition of Sr in the animal bones, which protects the milk and thus human bone.

Data for foreign soil samples collected just before the Castle test series are presented in Table 3 and Figures 4*a* and 4*b*. From these data we deduce that the band around the earth bounded by the latitudes 60° N. and 10° S. shows a deposi-

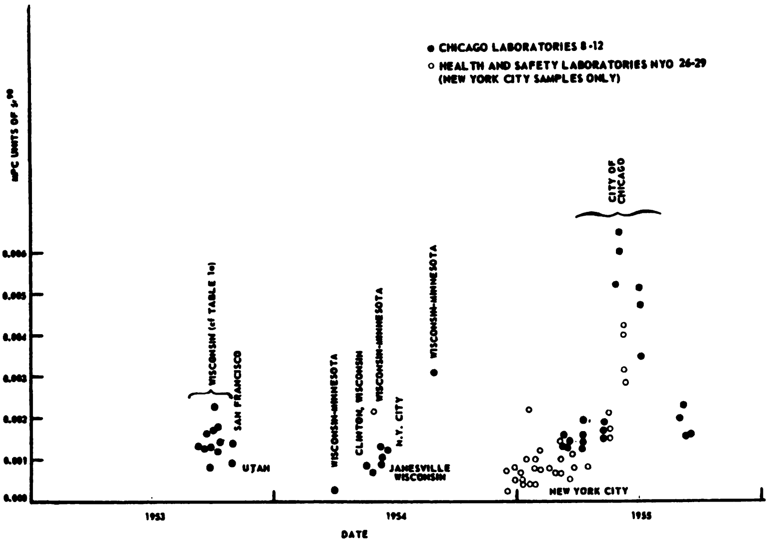

Fig. 1*c*.—U.S. milks—Sr^{90} content

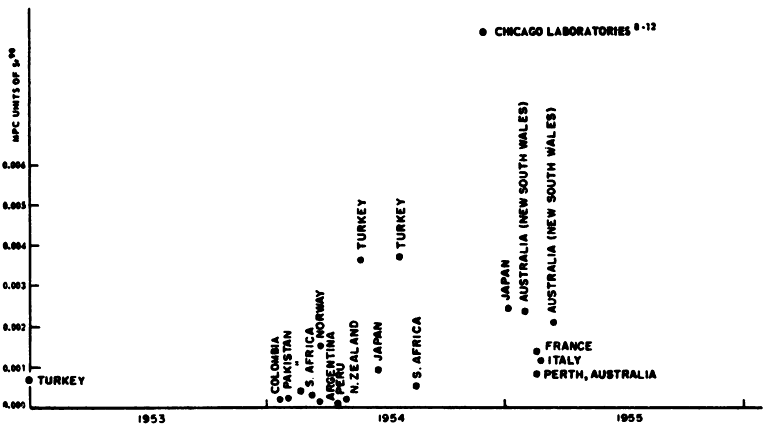

Fig. 1*d*.—Foreign milks—Sr^{90} content

tion of 0.8 megatons (MT) equivalent of Sr^{90}, in addition to some 0.4 MT which appears to be nearly uniformly deposited, as would have been expected from a slow deposition from a large stratospheric reservoir. No evidence for longitudinal variation is apparent in Figure 4*b*.

The actual heights of rise of the bomb clouds are the basis for the assumption that all distant fallout from megaton weapons occurs from a stratospheric reservoir, while that from those of lower yield occurs from the troposphere. Actually, the height of the tropopause varies with the season, so that the season must be con-

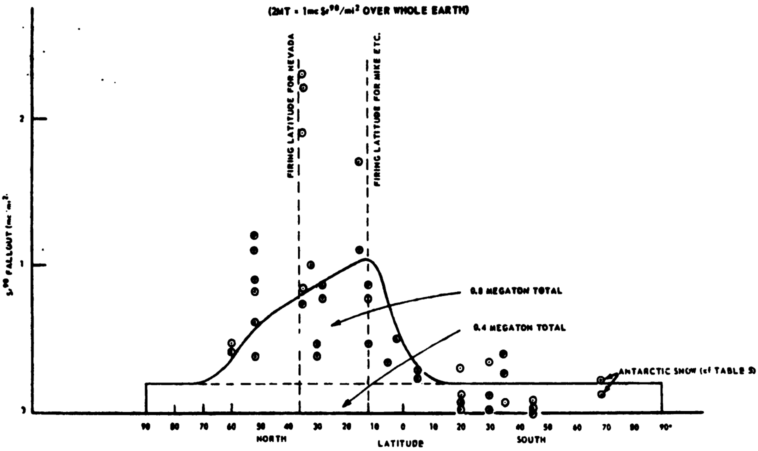

Fig. 4a.—Latitudinal distribution of foreign pre-Castle Sr^{90} fallout (soil assays)

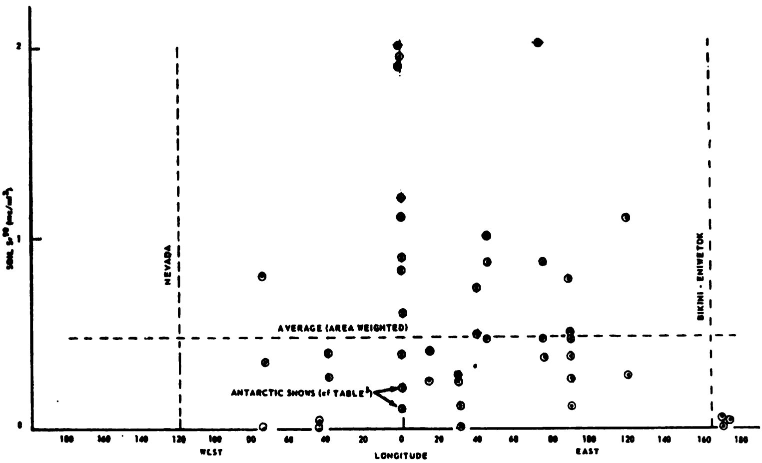

Fig. 4b.—Longitudinal distribution of pre-Castle Sr^{90} soil data from foreign samples.

sidered in the assignment. During the Pacific tests it has been near 55,000 ft.; hence our classification has validity in this respect.

Two of the most important data in Figures 4a and 4b are those from the antarctic series. The samples were snow cores, collected for the Chicago Sunshine

Laboratory and for cosmic-ray tritium analysis,[3–5] by Mr. Paul Humphrey of the United States Weather Bureau in January and February, 1955, at Admiral Byrd Bay (69°34′ S.; 00°41′ W.), at Atka Bay (70°35′ S.; 08°06′ W.), and at Little America III. The data are given in Tables 4 and 5. Table 4, Part A, gives the Sr^{90} and T contents of surface snow at four locations. From the T concentrations and the expected T production rate in this region[3–5] (T produced in the Castle test itself was precipitated out in a few weeks and never entered the Southern Hemisphere appreciably, because of the large amount of water taken into the cloud with which it became mixed[6]), we determined the annual precipitation to be 7.8 ± 2 inches of water. This calculation, together with that for the January–February,

TABLE 4

POST-CASTLE Sr^{90} FALLOUT IN ANTARCTICA

A. SURFACE SNOW

Date	Location	Sr^{90} (dpm/Liter)	T (Atoms/10^{18} H's)

1.52–2.16	3–4	0.41	0.90 ± 0.06	...	0.21

* Assumed annual precipitation, 7.8 inches water/yr, on the basis of T contents of surface waters (cf. Table 4).

1955, Sr^{90} precipitation rate of 0.8 mc/mi²/yr, are given in Part B of Table 4. The result for the annual precipitation agrees well with direct observation by the Atka Expedition and by Mr. Humphrey personally.[7] At Little America IV, direct observation showed that the floor of the tent projecting from the ice front was beneath only 7 or 8 feet of snow after roughly seven years. Since the density of the snow was about 0.35, this would correspond to about 5 inches of annual precipitation. Other observations[7] checked this general magnitude. In Table 5 a core taken at Admiral Byrd Bay was measured for both Sr^{90} and T. From these data we observe the pre-Castle fallout rates of 0.11 and 0.21 Sr^{90} mc/mi²/yr. The surface rate at this site is 0.43, which is less than the general average in the area for January and February, 1955, of 0.8 mc/mi²/yr—as shown in Table 4—hence it

may be that the pre-Castle values at this site are low also and should be increased by the ratio 0.8/0.43, or by 90 per cent, to 0.2 and 0.4, respectively.

The average Sr^{90} content of rain and snow in the Chicago area since the fall of 1952 was calculated by weighting each datum by the total rainfall observed in the particular storm. The data on the Sr^{90} content of Chicago rain are given in Figure 5.[8-12] It is clear that large fluctuations can occur in individual storms. However, these extremes were, in general, of low total rainfall; hence the effect on the average is small. It is interesting that the antarctic snows have about the same Sr^{90} content as the average Chicago rain of Figure 5. We recall that pre-

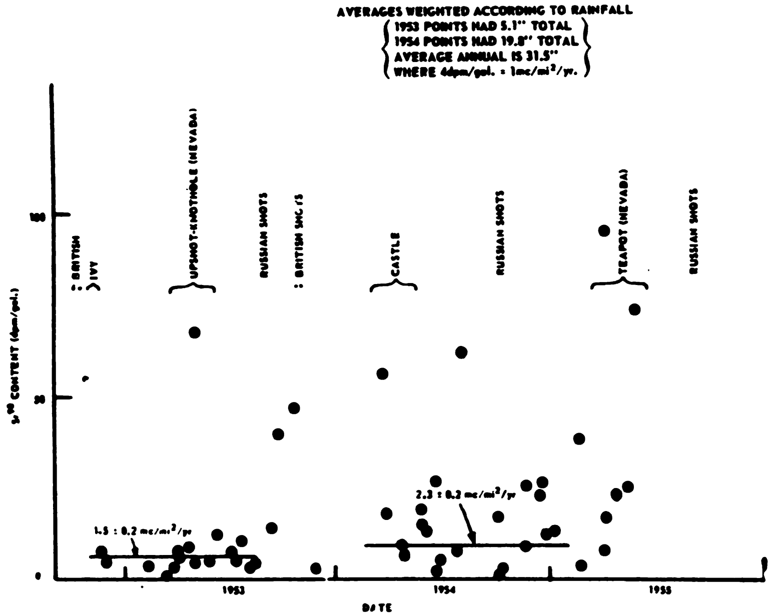

FIG. 5.—Sr^{90} content of Chicago rains

cipitation there is only one-fourth to one-fifth that in Chicago. According to the mechanism espoused in this paper, these fluctuations are to be expected, because the fallout from the stratosphere is thought to be steady and continuing, and the washing-out by rain is expected to carry down the fallout accumulated since the last precipitation from the particular air mass involved. Many of the samples given in Figure 5 and in Project Sunshine Bulletins Nos. 10 and 11[8-12] have been measured for T as well;[2-6] hence further correlations of the type described above for antarctic snow (Tables 4 and 5) can be made.

In Tables 1 and 2 the Sr^{90} contents of soils in the midwest region of the United States were shown to have an assay of 4.7 mc/mi² in October, 1953. The total from rains in the preceding year was only 1.5 mc/mi², according to Figure 5; hence we have to expect about 3 mc/mi² to have been deposited prior to Operation Ivy by direct fallout, most reasonably from tropospheric debris. The total fired in

Nevada prior to this time which would not have fallen out in the immediate vicinity of the test site was approximately 200 KT for the Operations Tumbler-Snapper and Buster-Jangle together. If this were all deposited in the United States, it would amount to about 7.0 mc/mi². The test series Upshot-Knothole, with approximately 220–230 KT of distant fallout, and Teapot, with approximately 160–180 KT, should have added correspondingly to the 4.7 mc/mi² in October, 1953, and to the 3.0 mc/mi² of stratospheric fallout for the intervening period, for a total of perhaps 12 mc/mi² expected in the spring of 1956 in the United States.

The efficiency with which rain removes fallout from the air through which it passes is probably high. One knows, on simple physical grounds, that as little as 0.1 inch of rain will traverse at least 90 per cent of the air volume lying below the layer in which the rain originates, so that 90 per cent of all particles which can be swept up by a falling raindrop will be carried down by such quantities of rain. On the point as to whether fallout is likely to be deposited by rain, we note that G. H. Wilkening[13] showed that the decay products of the radioactive gas Rn which in themselves are isotopes of nongaseous elements are found affixed to particles of diameters between 20 and 800 angstrom units (0.002–0.080 μ)—a submicroscopic range not at all unlikely for the radioactive fallout stored in the stratosphere.[1] The velocity of fall for such particles would be very small and in this respect quite compatible with the long stratospheric storage times indicated by the Project Sunshine data. Blifford, Lockhart, and Rosenstock[14] studied the concentration of the Rn decay products in rainfall in the Washington, D.C., area and concluded that rain was the mechanism by which the particles containing these products were precipitated and that the average time the decay products spent in the air before being precipitated was only 15 days, approximately. O. Haxel and G. Schumann,[15] found this time in Heidelberg, Germany, to be about 4 days, and Damon and Kuroda[16] concluded that Blifford *et al.*, were correct in attributing the precipitation of the aerosol carrying the Rn decay products to rain, their conclusion being based in part on additional data that they had taken. The average time spent by water in the air was found by von Buttlar and Libby[3] to be between 5 and 14 days.

For these reasons it seems very likely that rainfall or snowfall carries down a major part of the fallout which comes from the stratosphere and probably is a very important mechanism for that part of the tropospheric fallout material which does not fall out in the first few hours or day or two after the detonations. Of course, the whole question can be settled by direct experiment in which a correlation between rainfall and total fallout is sought. The present data seem to favor the hypothesis. This conclusion and prediction seem to be borne out by Table 6, which presents the total Sr^{90} content of the top 2 inches of typical United States soils collected in October, 1955, and leached at room temperature for 30 minutes with 6 N HCl.

Table 7 shows data obtained in the Chicago laboratories on the Sr^{90} contents of rivers and lakes. It is clear that these are much lower than those of the rain from which they are derived. For example, from Figure 5 we should estimate that the average rain in the Chicago area in the summer of 1953 had a Sr^{90} content of about 7 dpm/gal. From Table 1 for the domestic pre-Castle soil contents and from Figures 4*a* and 4*b* for foreign pre-Castle soil contents, we estimate that the European

rains averaged about 3 dpm/gal. The four rivers, Mississippi, Mosel, Seine, and Danube, show less than 5 per cent of this; hence we conclude that the Sr^{90} in rain is removed by the soil before the water runs off to the rivers and lakes. This fact agrees, of course, with the sharp localization of the Sr^{90} in the top 2 inches of soil (cf. Tables 1, 2, and 3).

TABLE 6*

Sr^{90} FALLOUT ACCUMULATION IN TOP SOIL (0–2 INCHES) IN U.S. IN 1955
(Sampled September 23–October 20, 1955)

Los Angeles	120 ± 12
Average	578
or	7.3 mc/mi²

(Probable additional Sr^{90} in lower layers and to be released by additional leaching probably will raise this about twofold.)

* Data by E. P. Hardy and R. S. Morse, of the Health and Safety Laboratory, New York Operations Office, personal communication.
† This datum was obtained by Dr. J. L. Kulp, Lamont Geological Observatory, Columbia University. The procedure was different from that of the New York Operations Office (personal communication).

TABLE 7

Sr^{90} CONTENT OF RIVER AND LAKE WATERS*

Location	Sr^{90} Content (dpm/Gal)	Location	Sr^{90} Content (dpm/Gal)
Lake Michigan, October 27, 1953	0.39 ± 0.08	Mosel River, Metz, September 7, 1953	0 ± 0.05
Mississippi River, Memphis, February 4, 1953	1.13 ± 0.16	Seine River, Nogent, September 8, 1953	0 ± 0.09
Mississippi River, St. Louis, April 17, 1953	<0.77 ± 0.18	Danube River, Ulm, September 12, 1953	0 ± 0.07

* See note to Table 2.

Examination of the data in Tables 2 and 3 on the Sr^{90} content of the exchangeable calcium in soils shows that there is a strong tendency for the lowest activity of Sr^{90} per unit weight of exchangeable Ca to occur in Ca-rich soils and vice versa, as would be expected, of course, if the fallout rate were uniform. This situation is displayed graphically for the pre-Castle soil data in Figure 6.

For years the Health and Safety Laboratory of the New York Operations Office of the Atomic Energy Commission (Mr. Merril Eisenbud, manager), with the co-

operation of the United States Weather Bureau, has been collecting fallout data[17] by use of gummed papers of 1-ft.^{2} area which are laid flat for a certain time out in the open away from buildings. After the exposure, the paper is folded and mailed to the New York Operations Office in an ordinary envelope. Samples thus can be collected cheaply, easily, and quickly from any populated area anywhere the postal service reaches. Most of the data so obtained have dealt with total fallout rather than with Sr^{90} specifically, but many analyses for Sr^{90} have been made since Operation Castle. These are presented later.

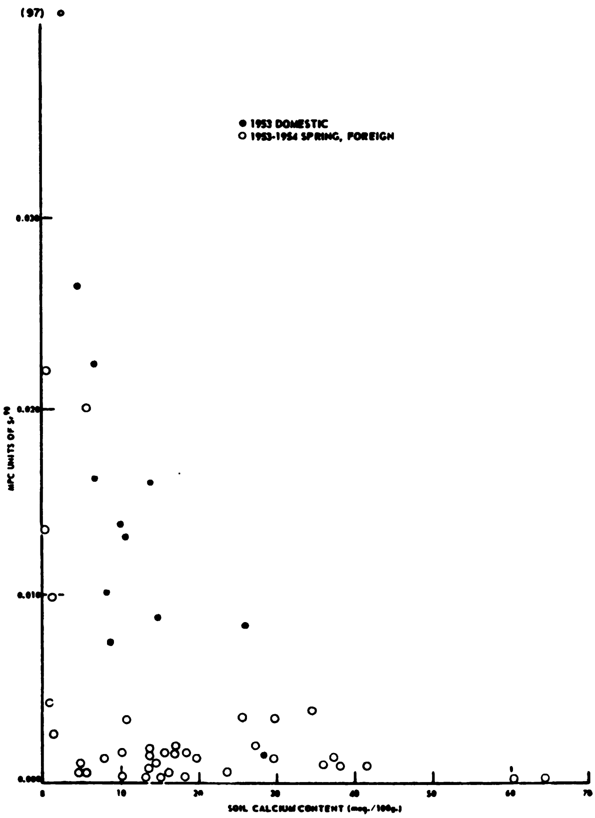

FIG. 6.—Top soil Sr^{90} concentration versus calcium content

The main question about the gummed-paper technique is its over-all efficiency of collection. In order to determine this, the Health and Safety Laboratory has conducted an extensive series of comparisons of the amounts of fallout by gummed paper and a 12-gallon pot with an 18-inch vertical cylindrical wall placed immediately beside the paper. Some of the data thus obtained are given in Table 8. From them we deduce a collection efficiency of 69 ± 9 per cent (but we use 63 per cent, since Mr. Eisenbud recommends this on the basis of more data and a better statistical treatment).

The data thus obtained for the post-Castle Sr^{90} fallout rate in the United States and South America are given in Table 9. These are combined with those for other areas, to give the world Sr^{90} fallout rates for September, October, November, and

December, 1954, presented in Table 10 and Figure 7. From these data we obtained these extremely important conclusions:

1. A Sr^{90} fallout probably derived from megaton weapons and nearly uniform over the world, except for local effects due to rainfall variations and to fallout from

submegaton weapons, seems clearly established. The fallout from the kiloton weapons lasts only a few weeks at most, since they involve only tropospheric

* 134 dpm/10^6 ft³ = 1 mc/mi²/yr (cf. text); (28300 ft³/ft² = 10^6 ft³/35.5 ft³).

Figure 8. In order to correlate these data with the fallout rate, we recall that, as remarked previously, any rain of 0.1 inch or more probably will thoroughly wash down the fallout in the air below the layer at which the rain originates. Examination of the weather data for the Washington, D.C., area in the period when the samples were taken shows that the average interval between rains was 6 ± 3 days. Therefore, the Sr^{90} content of surface air should correspond to fallout for this time on the average, and we would expect a fallout rate R (mc/mi²/yr) to correspond to a surface-air content of $R \times \frac{6}{365} \times 79 \times 41 \times 2.5$ dpm/10^6 ft³, since 79 dpm/ft² is equivalent to 1 mc/mi² and there are 41 ft²/10^6 ft³ below the tropopause on the average at Washington, D.C., and 2.5 is the average ratio of height of tropopause to rain-bearing layers. The resulting rate of 0.70 ± 0.2

mc/mi²/yr is definitely low, compared to the rain result of 2.3 ± 0.2 mc/mi²/yr for Chicago (Fig. 5) and of 1.5 ± 0.1 mc/mi²/yr for data involving gummed paper (Fig. 7 and Table 9). The uncertainty in the factor of 2.5 for the ratio of rain-bearing layer height is probably the principal uncertainty in the calculation of the fallout rate from air-filter data, though it may be that the perfect vertical mixing of the lower 40 per cent of the troposphere implicit in the calculation is an incorrect assumption, in that air right at the surface is cleaned to a considerable extent by surface contact with vegetation and water and soil and therefore has less fallout than the average for the lower troposphere.

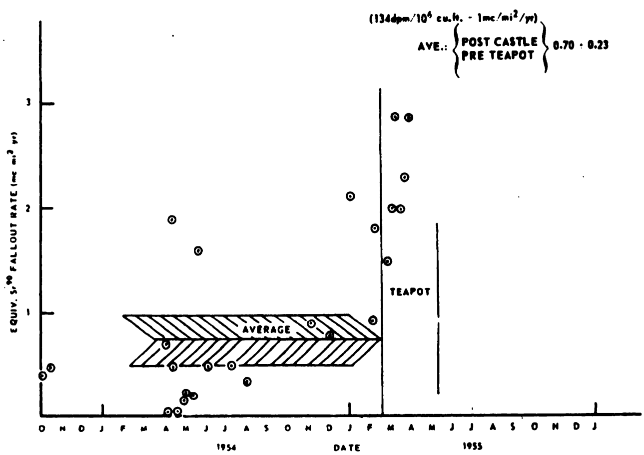

Fig. 8.—Sr^{90} in air, Washington, D.C.

From the data given on rates of fallout, we calculate the average stratospheric residence time, $\tau = 10 \pm 5$ years. The high-altitude data show a definite rise above the tropopause. This is strong confirmation for the stratospheric storage and dissemination mechanism.

II. DISCUSSION

A. Predicted Sr^{90} Fallout

The stratosphere reservoir of Sr^{90} immediately after Operation Castle had been completed was about 12 mc/mi². The fallout rate of Sr^{90} corresponds to an average storage time of 10 ± 5 years and essentially uniform world-wide dissemination. The radioactive half-life of Sr^{90} is 28 years, corresponding to an average life of 40 years. Therefore, the Sr^{90} fallout rate from tests up to and through the Castle series should be given by

$$R = \left(\frac{1}{10}\right) 12e^{-t(1/10+1/40)} \text{ mc/mi}^2\text{/yr}, \tag{1}$$

where t is the time elapsed, in years, since May, 1954. This relation is given in Figure 9. From it, we can predict the tropospheric air content to be

$$A = \frac{RT \times 2.5 \times 79 \times 41}{365} \text{ dpm}/10^6 \text{ ft}^3, \tag{2}$$

where a period of T days elapses between the rains washing out the air mass concerned. Taking T to be 6 days on the average, the surface air should contain 134 R dpm/10^6 ft^3 in the middle latitudes.

The rainfall content will be 4 R dpm/gal for regions with an annual rainfall of 31.5 inches. The concentrations of Sr^{90} per unit volume for other annual precipitations are to be derived by inverse proportionately, e.g., in Antarctica, where the annual precipitation is about one-fourth of 31.5 inches, the Sr^{90} content of snow should be given by 16 R, or

$$A' = 16 \times 1.20e^{-t(1/10+1/40)} \text{ dpm/gal}. \tag{3}$$

In this connection, it is very important to note that regions of frequent rainfall very probably will receive more Sr^{90} fallout than will more arid regions.

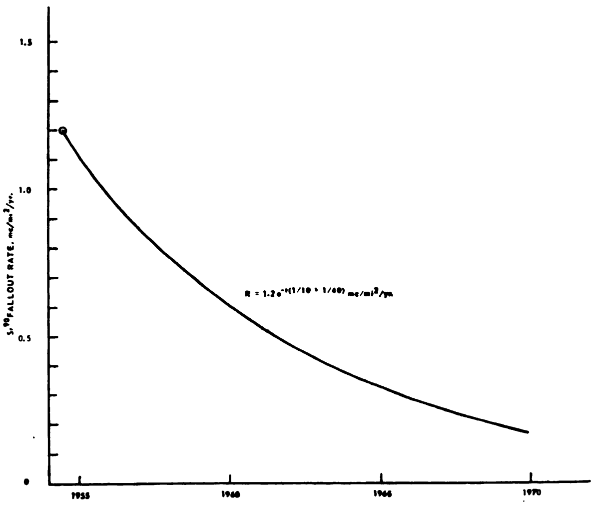

Fig. 9.—Predicted fallout rate for Sr^{90} formed prior to and during operation castle.

Of course, some fallout will be deposited by the surface winds blowing over the leaves of trees and grass. For example, the Naval Research Laboratory[10] has mounted an uncharged platinum screen vertically and held normal to the surface winds by a large vane. The deposition is by impact. Two weeks' total collections were made, and these gave up to 20 times as much as for gummed papers of the same area exposed for the same time in the same place. The screen was 80 mesh and probably passed about 0.5 × 10^6 ft.^{3} in the 2 weeks' exposure. From this it is clear that surface contact with fallout-laden tropospheric air must result in dep-

osition. Further evidence for this is seen in Table 1, where there is seen to be essentially no correlation between the Sr^{90} contents of soils and the crops of alfalfa grown on them. There obviously must have been very considerable direct dep osition on the surface of the plants. Also, the relatively low values for the Sr^{90} content of surface air found by the Naval Research Laboratory (Table 11), calculated with respect to the observed rain content, may very well be due to surface deposition by direct contact on tree leaves and grass.

The soil content will be the total of all fallout radioactivity, *less any natural weathering processes which serve to remove the fallout Sr^{90} from the chemically available form in which plants can assimilate it.* Neglecting this latter effect, although, as we shall see, there is reason to believe that such effects are operative in an important way, and taking the average for the exchangeable Ca content of soils over the world (cf. Tables 2 and 3), which is 8 gm/ft²/in. we calculate that the top 2.5 inches of soil, which in general holds nearly all the Sr^{90} (Tables 2 and 3), has some 20 gm of exchangeable Ca. Therefore, we predict that in the absence of curative weathering effects acting to remove Sr^{90} from contact with the biosphere, the average Sr^{90} concentration of exchangeable Ca, in MPC units, should be

$$S = \frac{0.0792}{2.2 \times 20}\left[P + \int_0^t R\,dt\right], \tag{4}$$

where P is the pre-Castle deposition of 0.8 mc/mi² in the middle latitudes and 0.2 mc/mi² world wide. Thus in the middle latitudes the Sr^{90} concentration of exchangeable soil Ca should be given in MPC units by

$$S = \frac{0.0792}{2.2 \times 20}\left[0.8 + 1.2\int_0^t e^{-t/10}\,dt\right]e^{-t/40} \tag{5}$$

or,

$$S = [0.0015 + 0.0213(1 - e^{-t/10})]e^{-t/40}. \tag{5'}$$

This result in terms of mc/mi² and MPC units is presented graphically in Figure 10. The maximum post-Castle Sr^{90} soil activity will be expected in about 1970. The present average should be about 0.005 MPC unit for soil with 20 gm. exchangeable Ca/ft². Those soils of low Ca content can, of course, have a much higher Sr^{90} content for unit amount of exchangeable Ca. Consider, for example, certain areas in Wales near Cardigan (cf. Table 3, Sample No. 54417), where the available Ca/ft² amounted to only 0.4 gm. and the specific Sr^{90} activity was found to be 0.097 MPC. For this area our analysis would predict a forty fold higher content than that given in Figure 10. This, of course, is reflected in higher contents for the bones of grazing animals.

The weathering processes which may operate to fix the fallout Sr^{90} and make it unavailable to the biosphere, such as the fixation in massive Ca deposits, are worthy of consideration. Only further investigation will reveal how important such processes are. The present Project Sunshine sampling program includes repeated sampling of given regions. The data so obtained should disclose any such trends. Some data already in hand seem to indicate such effects, but further confirmation is necessary.

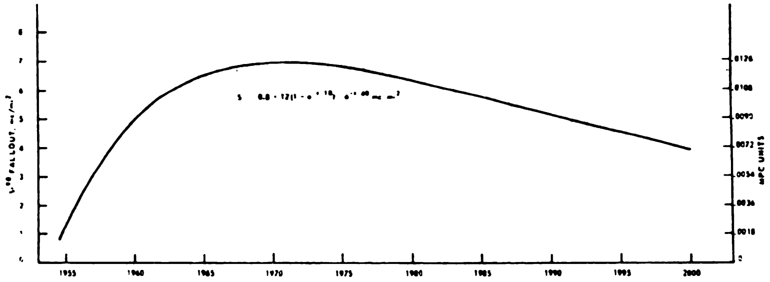

FIG. 10.—Predicted Sr^{90} in soil following Castle (Assumed Ca = 20 gms./ft²/2.5")

In addition, palliative measures may prove effective. For example, Nervik, Kalkstein, and Libby[19] have shown that milk can be purified for radiostrontium by a treatment which may well prove to be quite practical and inexpensive.

B. BIOSPHERE CONTENT OF Sr^{90}

It seems clear that there will be discriminatory barriers of some magnitude operating at each of the stages of transfer from the soil into the biosphere. Taking these stages in general to be

(1) Soil → Plants,
(2) Plants → Animals,
(3) Animals (milk) → Humans,

we consider the three corresponding barriers.

1. *Soil-to-Plant Transfers.*—In Table 12 the Sr^{90} contents of plants are compared with those for the soils on which they grew at a variety of localities just before Operation Castle. It seems clear that, on the average, plants have about twice the specific Sr^{90} content relative to Ca that the supporting soils do. It seems

TABLE 12

PRE-CASTLE PLANT Sr^{90} CONTENTS

§ E. A. Martell, *ibid.*, Suppl. 2, June 1, 1955.

very likely that this is due in part to fallout occurring directly on the external plant surfaces. This is further borne out by the lack of detailed correlation in Table 1 between soil and alfalfa results for eleven middle western United States farms. From this result, we may calculate that about half the total Sr^{90} content of alfalfa is due to direct fallout, while for general forage it is probably an even

higher percentage. This comparison is not quite accurate, because, although almost all the Sr^{90} is contained in the top 2.5 inches of soil, the Ca, on the other hand, is available to the entire depth of the root system. It is also recognized that the vertical distribution of the Ca may be nonuniform. There is no reason to expect preferential assimilation of Sr from the soil relative to Ca; hence the only other explanation for the data in Table 12 is direct fallout. As remarked in Section I in the paragraphs on rain and air-filter data, there are two mechanisms for direct fallout of the ultra-finely divided particulate matter carrying the Sr^{90} in the stratospheric reservoir—rainout and contact deposition after the fallout has entered the troposphere. Rainout appears to be the principal mechanism, though it has been demonstrated by the Naval Research Laboratory,[20] as mentioned earlier, that an 80-mesh screen mounted vertically to prevailing surface winds can gather more fallout than falls out directly on the average by all mechanisms. It is not clear, however, to what degree foliage acts in this way, but the probability seems high that the effect is relatively minor and that rainout, followed by drying of raindrops, is the main way in which the foliage surfaces gather fallout.

On this basis we conclude that total fallout in arid regions should be appreciably lower than in areas with normal rainfall. This effect seems to be borne out by the data available now, though more definitive experiments are needed. It probably follows also that regions subject to seasonal rainfall rather than relatively uniform precipitation all year should show less fallout for the same total annual rainfall. Also, regions subject to frequent morning fogs may be particularly high in total fallout. The Sr^{90} probably will enter the troposphere at relatively uniform rates, but the chance of precipitation will depend strongly on the local weather.

Of course, rainfall is necessary to plant growths, so that plants are certain to gather some fallout. However, for regions of low rainfall where irrigation is used—such as the Imperial Valley in California—the fallout content of the crops should be particularly low, for, as shown in Table 7, rivers are nearly free of fallout, since the soil purifies the runoff water before it reaches the rivers. Similarly, reservoirs and lakes will be low relative to rain because of dilution and the importance of runoff water from surrounding watersheds in replacing evaporative and withdrawal losses. It is also well to note that the ordinary water purification processes are effective in removing an appreciable fraction of the radiostrontium.

The by-passing of soil entirely, which occurs in the direct fallout on plant surfaces, of course means that the retarding effects of high Ca contents in soil are inoperative, and cattle grazing on such foliage may show little correlation in the Sr^{90} contents with the soil Sr^{90} activity for this reason. This appears, from the data in Table 1, to be true in the United States Midwest.

It is clear, however, that washing may reduce the level of fallout externally carried by plants, though direct leaf absorption will be expected to occur rather rapidly for water-soluble fallout. For the megaton weapons fired in the Pacific, the bulk of the fallout resides on particles of CaO or $Ca(OH)_2$ or mixtures of CaO, $Ca(OH)_2$, and $CaCO_3$ made by the great heat of the fireball acting on the coral of the islands and sea floor in the firing areas.[21] A large amount also is carried on NaCl particles. This material, therefore, should be quite water-soluble and should

be rapidly absorbed into the leaves. Washing therefore probably will not be particularly effective for the world-wide fallout, which derives from the Pacific tests. From weapons fired in the air, the particles probably will consist of less soluble oxides and therefore are more likely to wash off of plant surfaces before being absorbed.

Menzel,[22] of the United States Department of Agriculture, grew cowpeas on 42 American soils to which equal amounts of bomb debris had been added. Available Ca ranged from 0.7 to 48 milliequivalents of Ca/100 gm of soil. The Sr^{90}/Ca ratio of the plants was approximately inversely proportional to the available Ca in the soil over the full range of Ca availability. In another set of experiments on a particular type of soil (Evesboro) to which known amounts of Sr^{90} had been added at two carrier levels, the results listed in Table 13 were found. The distribution

TABLE 13

PLANT ASSIMILATION OF Sr^{90} FROM SOIL

Crop	(Sr/Ca) Soil (By Equivalents)	k_{Sr}	k_{Ba}
Barley	0.017	0.45	0.020
	0.0017	0.39	0.022
Buckwheat	0.017	0.49	0.023
	0.0017	0.43	0.028
Cowpeas	0.017	0.53	0.057
	0.0017	0.37	0.053

factor, k_{Sr}, defined as (Sr/Ca)plant/(Sr/Ca)soil, indicates the discrimination which the plant makes between Sr and Ca uptake. Similar tests were made for Ba.

By combining these data, Menzel concluded, as shown in Table 13, that the average Sr uptake from American soils was best fitted by a distribution factor of $k_{Sr} = 0.36$. This average probably will apply world-wide about as well.

2. *Plant-to-Animal Transfer.*—The Sr^{90} contained in grass and foliage eaten by grazing animals will be retained to an extent dependent on the metabolism of the animal. For example, for a 1-year-old steer[23] 30 per cent of the Sr^{90} fed orally was retained with essentially no discrimination relative to Ca. There appears to be a higher retention, approaching 90 per cent, for intravenous injection of young rats.[23] High Ca diets reduce the Sr^{90} uptake for rats, adult rats take up about 16 per cent of the ingested Sr^{90} on the same low Ca diet for which the young rats took up 73 per cent.[23]

Comar[24] has performed experiments on cows in which the Sr/Ca ratio in feed, blood, and milk was measured under equilibrium conditions. Typical relative values were 1.0, 0.37, and 0.13, respectively, thus indicating a relative lowering of the Sr^{90} content of the milk relative to the feed. This is borne out by direct observation on the fallout, as seen in Table 1, where for the Chicago milkshed the milk averaged 0.0014 MPC, while the alfalfa fed averaged 0.0089 MPC.

3. *Milk-to-Human Transfer.*—This ability of the cow to reduce the Sr^{90} in the milk relative to the feed is important as a barrier to human ingestion of this fallout radioactivity. With it in mind, we can expect that human Sr^{90} burdens should be 20 per cent or less (for older people) of the plant contents and about equal to the milk and cheese levels if the entire Ca in the body were assimilated at a given Sr^{90} content of the milk.

Since the Sr^{90} content of the whole biosphere is continually rising, about as shown in Figure 10, the average Sr^{90} content of milk should rise in a similar manner. Therefore, the intake of Sr^{90} by humans is steadily increasing, as shown in Figures 1*a*, 1*b*, 1*c*, and 1*d*. The data in Table 3 and Figures 1*c* and 1*d* show that the milk level at the time of Operation Castle averaged about 0.001 MPC, peaking in the middle latitudes, as did the soil assays (cf. Fig. 4*a*). This value shows a ratio of about 0.7 for the milk level to the average soil level for the top 2.5 inches of soil with 20 gm. of contained available Ca/ft^2. This high value probably is due to leaf pickup of fallout. Taking this as a general result, we predict the world values for milk and cheese at about 70 per cent of the soil values given in Figure 10, plus any local fallout. This would mean that we would expect average foreign milk and cheese samples to show about 0.004 MPC at the present time.

The human bone, of course, is formed during the growing process, so that the Sr^{90} content of children should be higher than for adults. The data[2, 8–12, 25] verify this prediction; however, for newborn babies there is less Sr^{90} than corresponds to the milk, showing the retarding effect of the mother's older Ca pool. Children seem to carry Sr^{90} approximately equal to the average level of the milk during the period of their lives. Adults decrease in Sr^{90} concentration with age as expected. It seems that the adults of the future will have Sr^{90} levels corresponding to the milk levels during their lifetime weighted according to their rate of growth. For example, the years from 10 to 18 will be most important for men and from 6 to 12 for women. Foreign children born now, according to Figure 10, should develop about 0.011 MPC unit during their lives. Children born now in the United States will develop a somewhat higher level, due to somewhat higher milk levels.

CURRENT RESEARCH FINDINGS ON RADIOACTIVE FALLOUT

BY WILLARD F. LIBBY

UNITED STATES ATOMIC ENERGY COMMISSION, WASHINGTON, D.C.

Communicated October 17, 1956

I. INTRODUCTION

The radioactivity produced by the fission reaction, being due to a mixture of many different fission products, changes its characteristics continuously and rapidly following release by the bomb detonation. Thus the conditions of firing are of extreme importance in determining the fallout effects. The intensity of radiation is enormously greater soon after the detonations, decreasing about tenfold for every seven fold increase in age. Since the time required for ingestion into the body is long, ingestion is unlikely for the shorter-lived fission products, and therefore the principal hazards for close-in fallout are radiation exposures by gamma radiation of the whole body and by beta radiation on the skin.

In the longer times, weeks and months after the explosion, the ingestive hazards begin to become important. The most serious of these is the high-yield fission product, radioactive strontium (Sr^{90}), which because of its own radiation and those of its short-lived daughter, yttrium 90 (Y^{90}), and because of its chemical similarity to the bone-building element, calcium, finds itself deposited in bone structure. Other radioactivities produced would be as bad if they spent as long a time in the body or if their radioactive lifetimes were long enough or if they were produced in high yield. Strontium has all these characteristics. Hence for the fission products which have survived the first weeks, the most important fallout constituent and the one most seriously to be considered is Sr^{90}. Neither radiostrontium nor its yttrium daughter emits gamma radiation, but only beta radiation. After the first-year cesium 137 (Cs^{137}), with half-life of thirty-three years, is the principal source of the residual gamma radiation, and any gamma radiation exposures due to fission products which are more than one year old are due very largely to radioactive cesium. In fact, old fallout can be thought of as a mixture of roughly equal radiation intensities in millicuries of radioactive Sr^{90} and radioactive Cs^{137}. The other isotopes either constitute no ingestive hazard or fail to emit gamma radiation in appreciable intensity. Thus, the hazards of world-wide fallout reduce themselves largely to the ingestive hazard of radioactive Sr^{90} and the external exposure from radioactive Cs^{137}.

The mechanism by which atomic-weapon debris is disseminated leads to three kinds of fallout. First, there is the strictly *local fallout*, which is due to the return to earth of the larger particles in the fireball. These may have their origin in the dirt, the soil, or tower structures which are taken into the fireball and either wholly or partially vaporized. The fraction of the total which falls out locally depends very much upon the conditions of firing. The most serious factor is the degree of contact of the fireball with the surface; another is the nature of the surface. For example, soil appears to be much more effective than water in producing local fallout.

Experience has shown that an atomic device exploded on the surface distributes about 80 per cent of its fission products on the ground within a few hundred miles of the burst point. A somewhat larger percentage takes part in the close-in fallout from an underground burst, and a smaller percentage will be scavenged from a near-surface burst or tower shot.

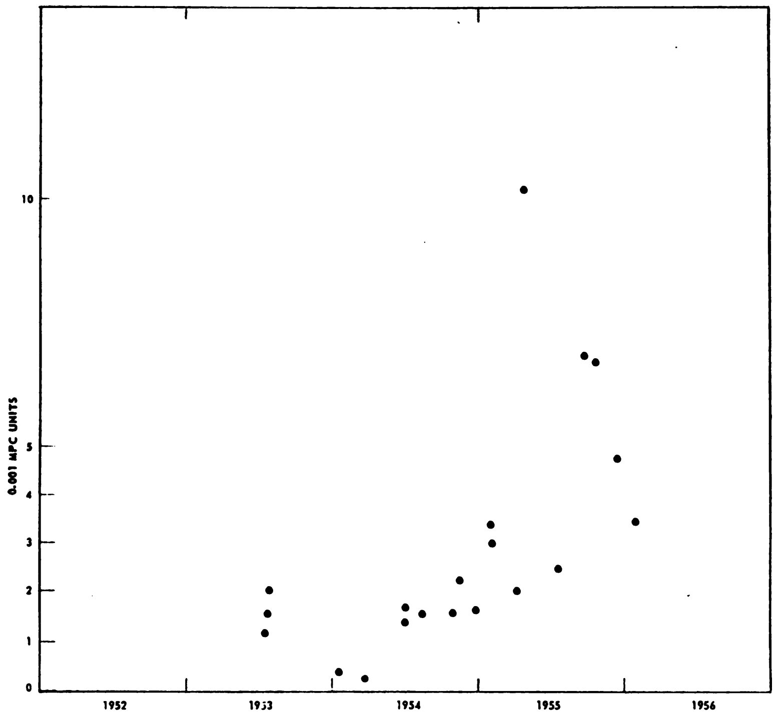

FIG. 1*a*.—Wisconsin cheese, Sr^{90} content

The tower shot is, in a sense, a special case of a surface burst, since the material of the tower itself is mixed with the fission products in the fireball to a greater or lesser degree, depending on the yield. Experience with tower shots indicates that even in cases where the fireball does not touch the ground a few per cent of the radioactive fission products come down as close-in fallout.

The fraction which takes part in the close-in fallout from a surface burst over deep ocean water appears to be somewhere between 20 and 50 per cent. This is less than the fraction of close-in fallout occurring from a corresponding surface burst over land, due to the evaporation of many of the drops before they reach the ground. Presumably this fraction is also affected by the prevailing humidity and temperature structure of the atmosphere through which the drops must fall. As the depth of the water is decreased, the point is reached where the fireball extends downward to the bottom and picks up bottom material. In such shallow water one would expect a higher percentage of close-in fallout than in deep water. Ex-

perience in the Pacific indicates that such is indeed the case and that in fact there would be very little difference in the fallout between a large-yield device in very shallow water and a true surface shot.[1]

The second type of fallout is the material which, though not coarse enough to fall of its own weight in the first few hours, is, nevertheless, left in the lower layer of the atmosphere, known as the *troposphere*, where ordinary weather phenomena occur. It is now well established that fallout particles are removed from this lower layer of the atmosphere in the first month or so; therefore, the tropospheric

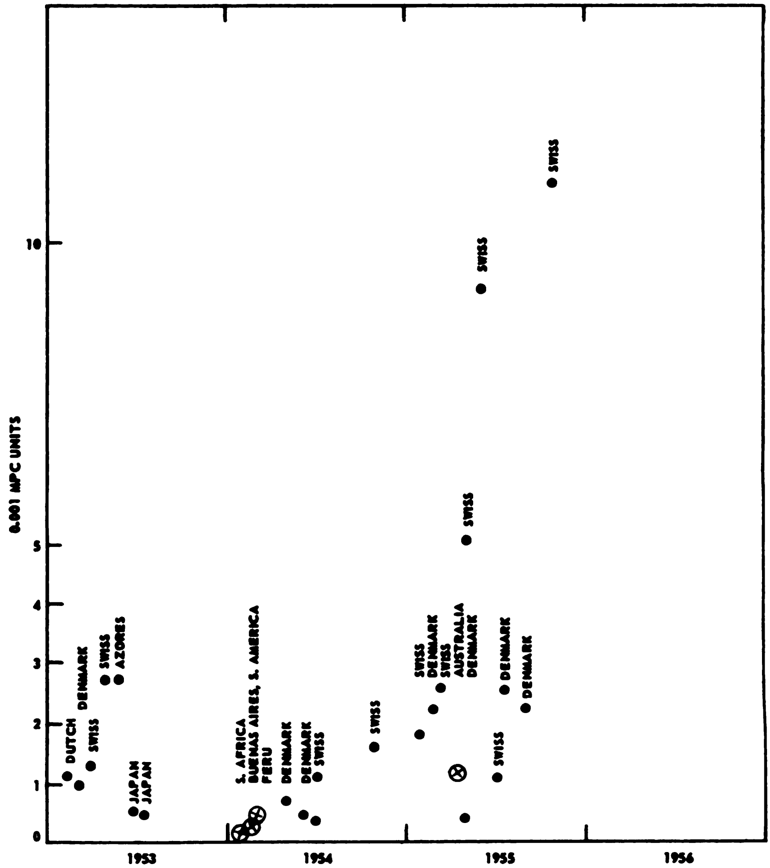

Fig. 1b.—Foreign cheese, Sr^{90} content (*crosses:* Southern Hemisphere)

fallout stays airborne at most a matter of a month or two before being deposited. Of course, in this time, it will in general move great distances, possibly even all the way around the earth; but, in general, it stays in the general latitude in which the explosion occurred. So the second type of fallout, the tropospheric world-wide fallout, produces a band of radioactivity in the general latitude of the firing site.

The fraction of the fallout in this category depends mainly on the bomb yield and the conditions of firing. A bomb which is fired on the ground produces a maximum of *local fallout*, naturally leaving less for the world-wide fallout of either the tropospheric or stratospheric variety. The bomb yield determines the division of the world-wide fallout between the two kinds of world-wide fallout. A general rough rule is that a 1-megaton bomb will produce clouds which push into the higher layer of the atmosphere, the stratosphere, before disseminating and that the clouds from bombs of less than 1 megaton will tend to stay mainly in the troposphere. Thus we see that a 500-kiloton weapon fired so its fireball did not touch the ground would

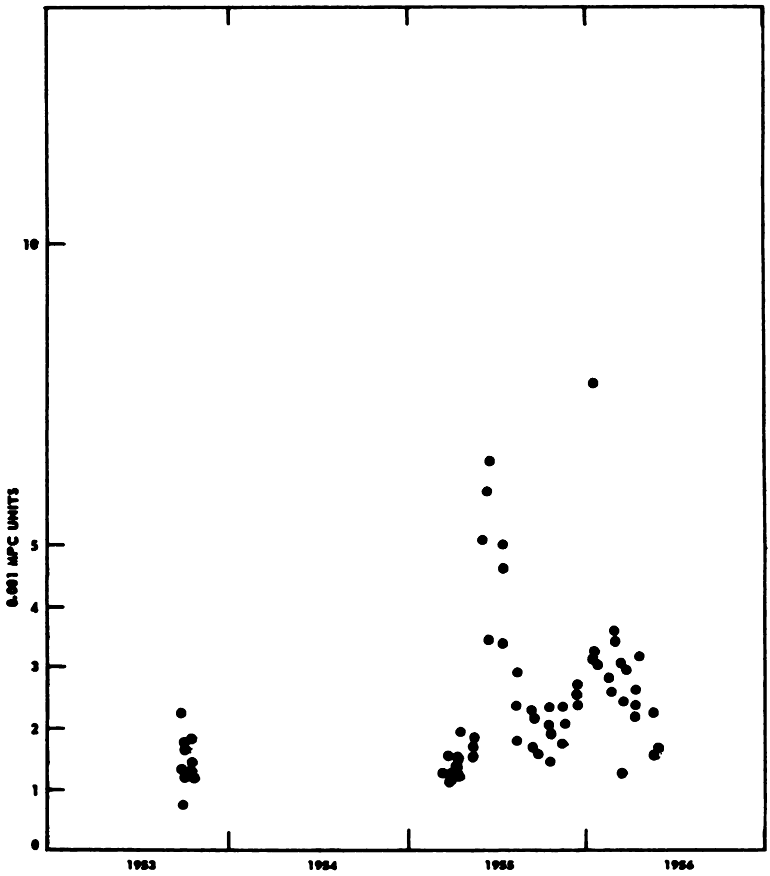

FIG. 1c.—Chicago Milk, Sr^{90} content

be expected to put the major part of its radioactivity in a band stretching around the world in the general latitude of the firing site. The distribution of the activity would be world wide and would be completed within the first month or two. Similarly, the same bomb fired in contact with the earth with ordinary soil would have a

large fraction—something like 80 per cent—of its fallout deposited within the first few hours within a few hundred miles of the test site, and the rest of the material would be spread in the tropospheric world-wide fallout pattern in a band around the earth in the same general latitude.

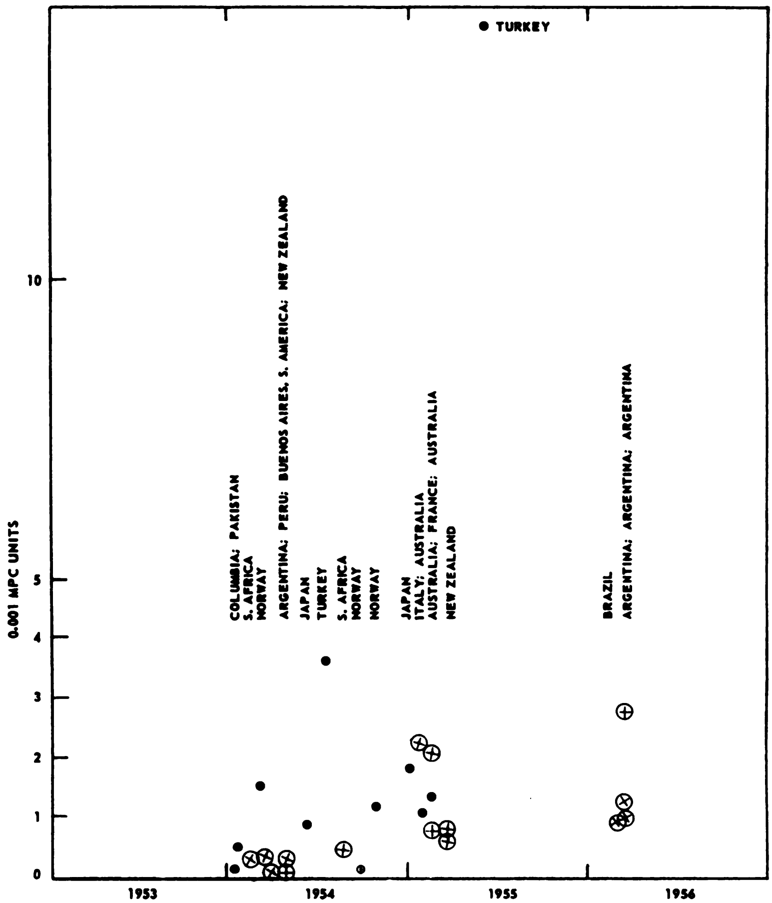

FIG. 1*d*.—Foreign milk, Sr^{90} content (*crosses:* Southern Hemisphere)

The third type of fallout is the *stratospheric world-wide fallout.* Weapons of yields of 1 megaton and greater thrust their radioactive clouds into the stratosphere, and the material which does not fall of its own weight within the first few hours is then very largely borne in the stratosphere for great lengths of time. An average time seems to be about ten years or somewhat less. A small amount of tropospheric world fallout is also produced, presumably due to a small fraction of particulate matter which is of just the right size to descend in a matter of weeks. The division into the two types, the *local* and the *stratospheric world-wide,* is very sharp and

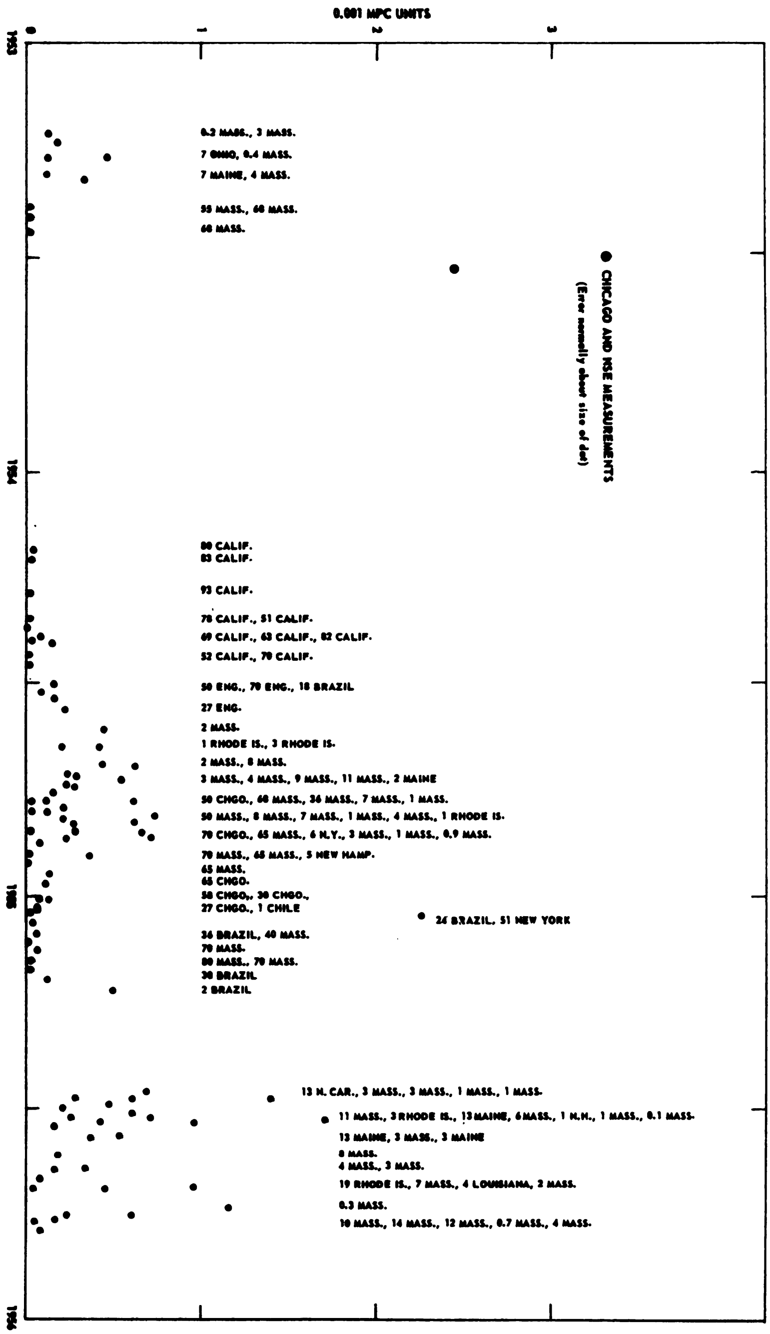

FIG. 2a.—Human bone, Sr^{90} content

marked, however, and to a very considerable approximation one can say that the megaton weapons yield the bulk of their fallout in these two categories. A weapon involving 1 megaton of fission would, if fired in the air, place most of its radioactivity in the stratosphere, and this, in contrast to the tropospheric fallout, appears to be

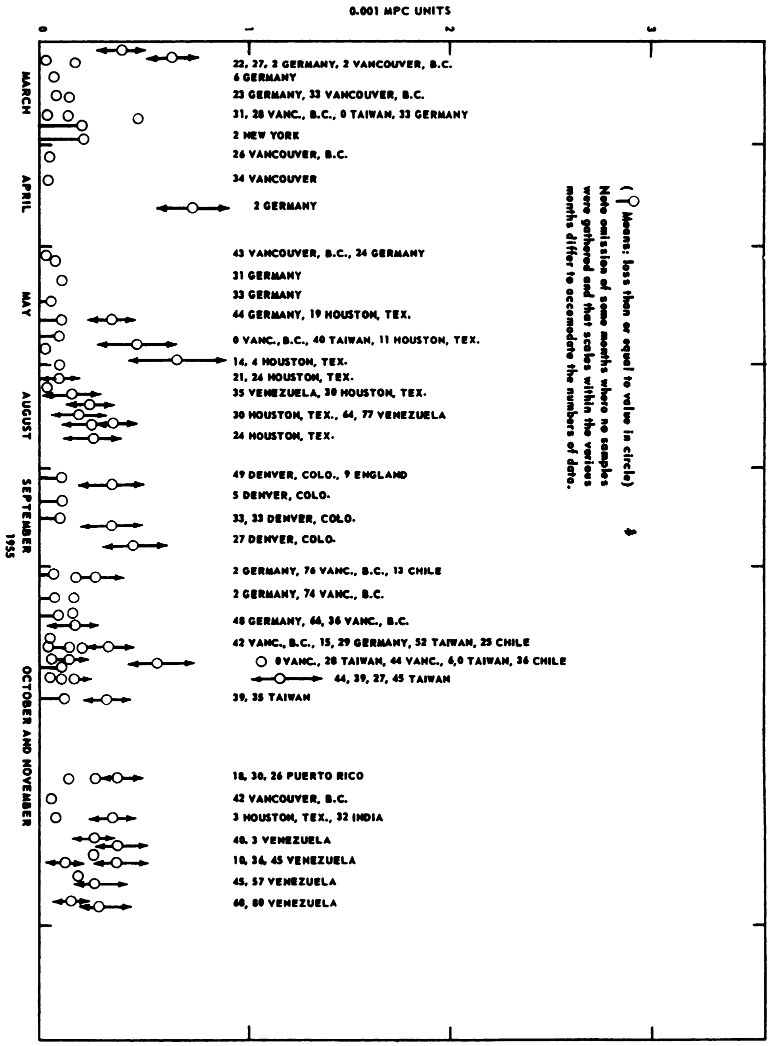

FIG. 2b.—Human bone, Sr^{90} content, Lamont measurements

widely distributed latitudinally and does not descend through the tropopause into the troposphere until months and years—an average time of about ten years—have elapsed. The resultant pattern of fallout appears to be essentially in approximately uniform world-wide distribution. The long time spent in the stratosphere is proba-

bly due to the absence of such scavenging agents as rain or snow, so the particles either must fall out of their own weight or diffuse downward by slight eddy motion, either of these processes being of their very nature slow. After passing through the tropopause into the troposphere, they will be rained out rather quickly in a matter of days or weeks. Because of the long residence time in the air, this type of fallout is particularly harmless as a gamma-ray hazard, since only the Cs^{137} is left. The amount of Cs^{137} is about the same in millicuries as the Sr^{90}; thus 1 megaton of fission thus distributed throughout the stratosphere would yield about 1/2 mc/mi^2 of either Sr^{90} or Cs^{137}. Just as in the case of Sr^{90}, the rate of deposition of about 10 per cent of the reservoir per year corresponds to a stratospheric fallout rate of Cs^{137} of 0.05 mc/mi^2/yr in the beginning. This rate decreases to half, or 0.025 mc/mi^2/yr, at about seven years, as the stratospheric reservoir becomes depleted.

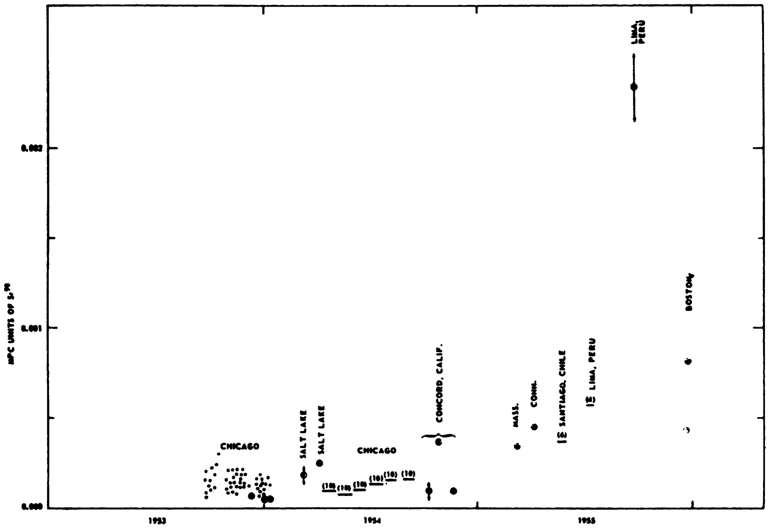

FIG. 2c.—Human stillborns (measurements by Chicago laboratories) (error less than 0.00005, unless otherwise indicated; parenthetical numbers are number of cases used for the average)

After the Castle test series was completed, there were about 24 megatons of fission in the stratosphere, corresponding to about 12 mc/mi^2 of Sr^{90} on the average and about the same amount of Cs^{137}. The subsequent stratospheric world-wide fallout rate appears to have been a little over 1 mc/mi^2/yr all over the world. In addition, of course, local fallout and tropospheric latitudinally localized world-wide fallout have occurred from subsequent weapons tests by the Russians and the Redwing series completed last summer at the Eniwetok Proving Grounds.

II. RESEARCH FINDINGS

A. Amount of Fallout and Expected Sr^{90} Body Burden from Weapons Fired to Date.—Since our last report,[2] further data on the actual magnitude of fallout in various places in the world and in various selected spots in the food chain have be-

come available. We shall summarize the results. Some human bone now contains radioactive strontium at levels of about one-thousandth of maximum permissible concentration (0.001 MPC; the MPC is 1 microcurie of Sr^{90} for the standard man and proportionally less for children, and is the maximum permissible concentration) in the northern latitudes where the bombs have been fired and the world-wide tropospheric fallout has occurred. There is evidence in the data on human material that age is a factor, e.g., older people who have had their calcium deposited

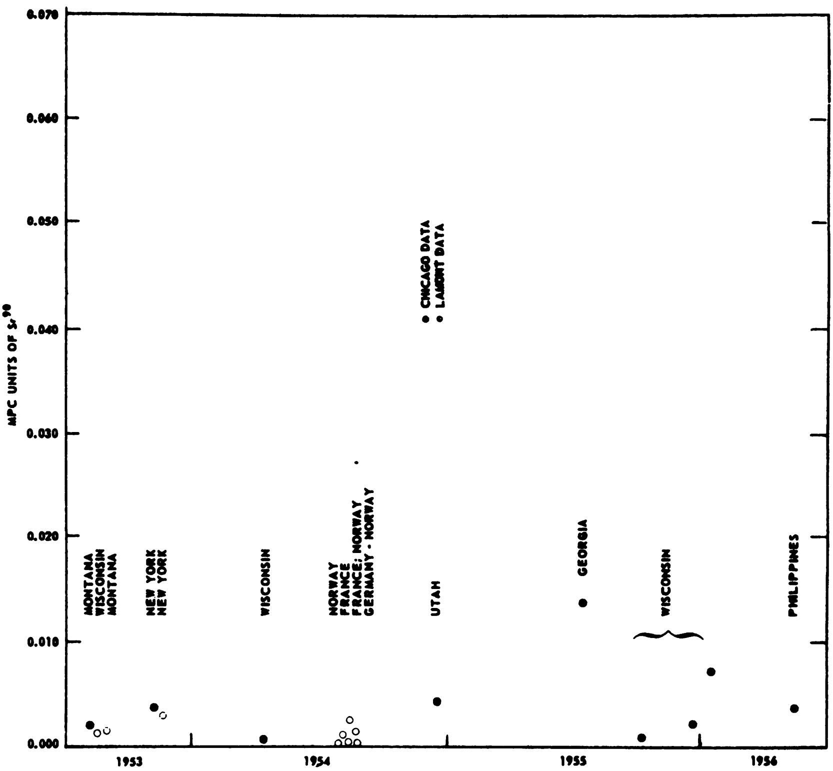

Fig. 3a.—Calf bones

prior to the weapons tests show lower concentrations, though in some instances exceptions to this rule are to be found. Lower levels are found in the Southern Hemisphere, where the major contamination is due solely to the world-wide stratospheric fallout, which in the northern latitudes of 10°–50° N. is generally less than one-half or one-quarter of the total fallout. The deposition in the human body seems roughly to parallel the levels of the total fallout. More data are necessary to validate this point fully.

At the end of 1955 the total deposition in the upper Midwest of the United States was some 13 mc/mi² of Sr^{90}. In the spring of 1956 this total rose to about 16 mc/mi².

Between May 5 and mid-July of this year, Operation Redwing was conducted at the Eniwetok Proving Grounds in the Pacific. Particular attention was paid to the fallout problem in this operation, and a major effect was made to produce a megaton-range weapon with an inherently smaller amount of fallout for a given energy release. This effort was successful. In addition, considerable attention

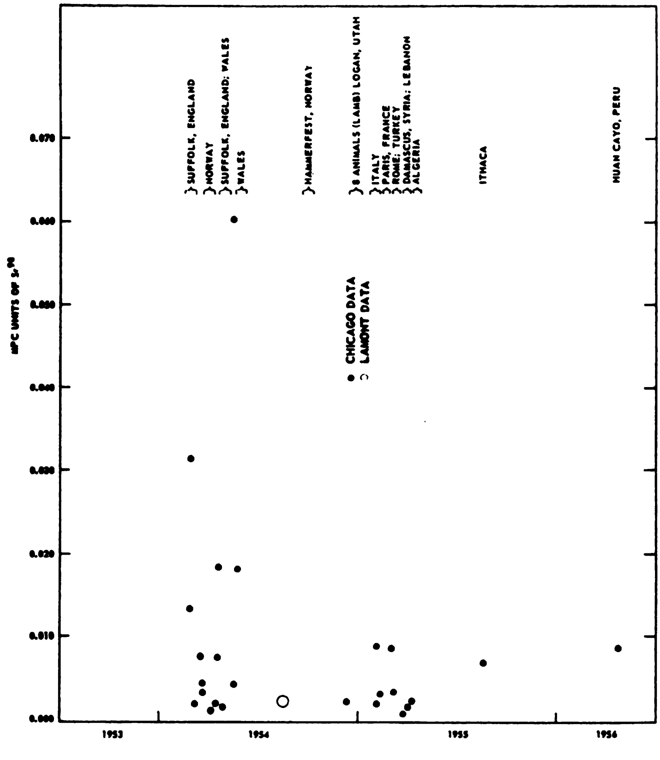

FIG. 3b.—Sheep bones

was paid to operational factors which would minimize world-wide fallout. Thus the total deposition in the stratosphere during this operation was held to a figure very considerably less than that present in the stratosphere before the operation. In fact, we estimate at the present time that the total stratospheric reservoir, counting all sources, is about the same as it was two years ago, i.e., 12 mc/mi² or Sr^{90}, or the equivalent of 24 megatons of fission, calculated as a uniform world-wide distribution. During the last two years the additional depositions in the stratosphere have amounted to about 6 megatons equivalent of fission products total, or 3 mc/mi² of Sr^{90} or Cs^{137}. This appears to have compensated approximately for the 10 per

cent per year of fallout and the 2.5 per cent per year of radioactive decay. In other words, the testing by all countries seems to have restored the stratospheric reservoir to approximately the 24-megaton value of two years ago.

The latitudinal tropospheric world-wide fallout, which is maximized by weapons of high yield which do not puncture into the stratosphere, is increasing. Several such weapons have been air-fired abroad in the last months. This material, for the reasons explained above, descends rather rapidly but all the way around the world in the same general latitude as the firing site. Thus, though it is difficult to estimate, it appears that this amounts to perhaps 5 additional mc/mi^2 of Sr^{90} and Cs^{137} in the United States. Adding to this about 1/2 mc/mi^2 for the world-wide tropospheric fallout from Operation Redwing and 1 mc/mi^2 for stratospheric fallout, we would estimate at present that a total of about 22 mc/mi^2 or Sr^{90} is to be found in the soils of the midwestern United States and that perhaps 15–17 mc/mi^2 is the total to be expected for similar latitudes elsewhere in the world, the difference being due to our proximity to our own weapons testing site in Nevada. These 22 mc/mi^2 of Sr^{90} in the soil of the United States amount to about 0.040 MPC units in the top two inches of soil, where most of the fallout is absorbed.

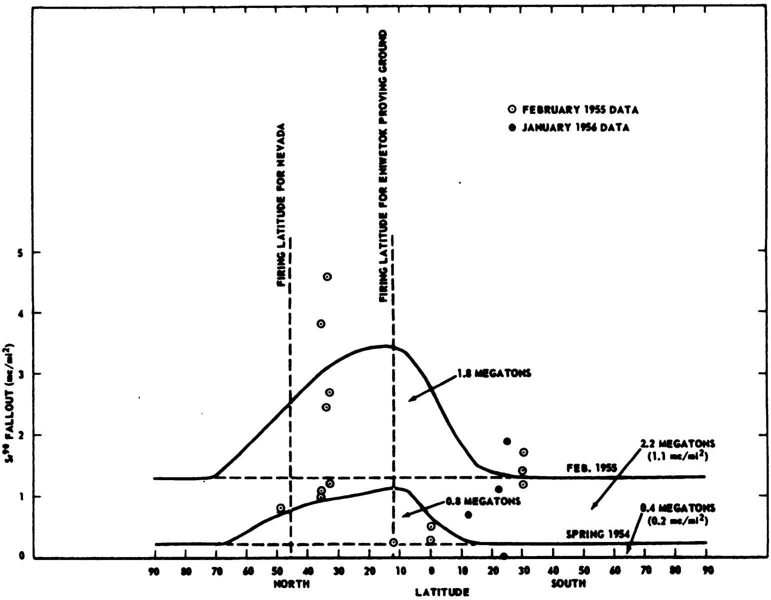

FIG. 4.—World-wide fallout, Sr^{90}, spring, 1955. Latitudinal distribution of foreign post-Castle Sr^{90} fallout (soil assays).

As of the present time, considering the latest human-bone and milkshed data, both domestic and foreign, together with the total fallout figures for corresponding periods, we find that the level of somewhat less than 0.001 MPC units now found in the bones of young children is to be compared with a total Sr^{90} fallout in the soil of about 12 times higher concentration. Additionally, laboratory data have shown that there is a threefold discrimination against strontium as compared to calcium in the assimilation by plants from the soil and that a further factor exists of about

eightfold discrimination against strontium relative to calcium in the excretion of strontium in milk as compared to the cow feed. Earlier,[2] it seemed reasonable to conclude that the human-body burden of Sr^{90} might well be as high as 70 per cent of the concentration in the top soil on which people live. The further evidence just

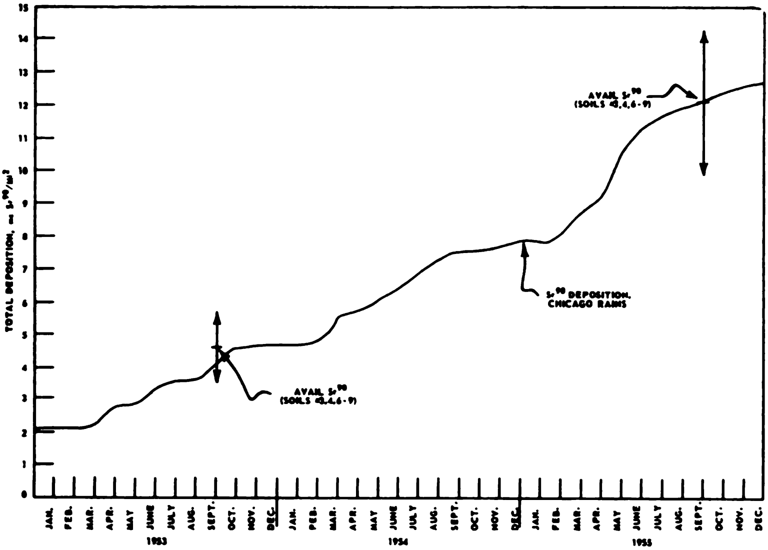

FIG. 5.—Sr^{90} fallout history, Chicago milkshed area

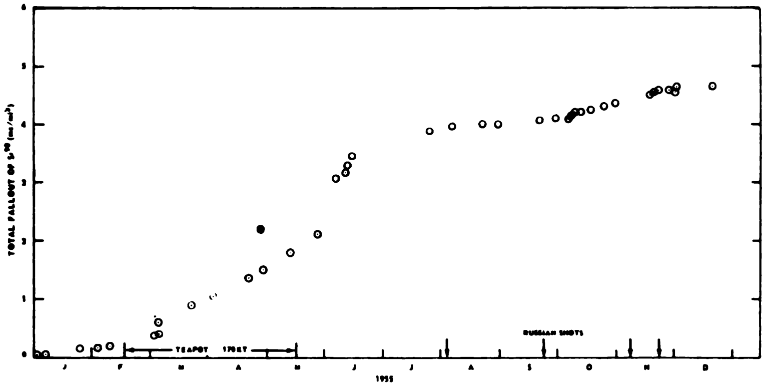

FIG. 6.—Total Sr^{90} fallout in Chicago in 1955 (Pot collection)

cited seems to indicate that this figure is much too high and possibly should be reduced to about 10 per cent. A strict application of the two discrimination factors described would give 4 per cent. Leaf retention of fallout which bypasses the soil causes the figure to be higher. Therefore, at the moment, we would expect that the body burden for children born now in America eventually would amount to be-

tween 0.004 MPC units, corresponding to 10 per cent of the top-soil concentration, and possibly a figure two or three times higher. The stratospheric deposition would be expected to continue at the expected rate, which at the present is about 1.2 mc/yr, so that some fifteen years from now, in the early 1970's a maximum additional total stratospheric fallout of about 6 mc/mi^2 will have occurred. In the meantime, the present 22 mc/mi^2 would have been reduced to 15 by radioactive decay, just about compensating for the stratospheric deposition. Thus the conclusion that the body burden in the United States from weapons fired to date would be about 0.004 MPC units, or possibly as high as 0.010 MPC units, seems justified. This level probably will not be exceeded in other countries unless particular factors of environment intervene, since the United States probably has the highest total fallout in the world. It seems very unlikely, however, that environmental factors could increase the level over the United States by more than a factor of 2 or 3.

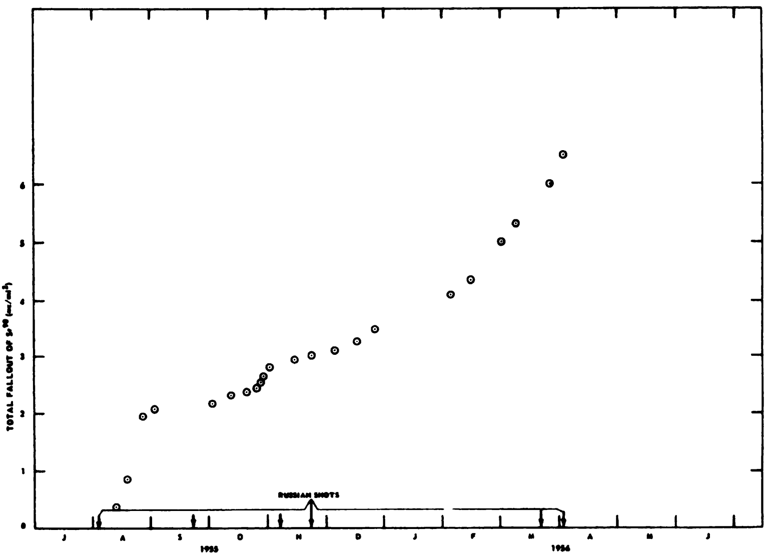

FIG. 7.—Total Sr^{90} fallout in Pittsburgh in 1955–1956 (Pot collection)

B. *Effect of Rainfall.*—As mentioned earlier, there is excellent reason to suppose that the deposition from the troposphere on the earth's surface is best accomplished by rain. By rain is meant not heavy rain but anything which involves the settling of water droplets. This might include fog or mist. The suggestion has been made[8] that the small size of the stratospheric fallout particles gives them a very high mobility due to molecular motion, since, in fact, they probably are almost molecular in dimensions. This high mobility of the particles makes it probable that direct contact of the fallout particles with water droplets will occur. One imagines on this theory that the tiny particles pass through the tropopause from the stratosphere and then meet water droplets in a cloud or mist or rain in the course of their rapid random motion due to collisions with the air molecules. Thus,

rather than the classical Langmuir mechanism of the rain sweeping out the air through which it falls by colliding with the particles themselves, the particles probably collide with the water droplets either before or during the rainstorm, probably most importantly before. It is clear from this mechanism that fog and mist may well be very effective and that a cloud probably gathers a considerable fraction of the fallout from the air in its bulk.

In any case, some experimental evidence has been found for the effect of rainfall on fallout by studying three particularly arid regions: the Imperial Valley in California at the town of Brawley and the western coast of South America at Antofagasta, Chile, and Lima, Peru. The soil in Brawley was sampled in January of this year and found to contain less than 0.6 mc/mi^2 of Sr^{90}. In order to realize the significance of this number, one should recall that we would have expected about 13 mc/mi^2 as an average figure for the United States. It is true that a considerable part of this is from the Nevada tests—the depositions of which occur mainly in an easterly direction and might well miss southern California—but it certainly seems that at least 8 mc/mi^2 would have been expected in the Imperial Valley under normal conditions such as prevail elsewhere in the United States and in Europe and Asia. Thus the observed fallout is not over a few per cent of that expected normally.

	Average Sr^{90} (mc/mi^2)		12.0	4.5		

* Had been plowed to 6" depth.

In addition to the soil samples, tests were made on the vegetation grown at Brawley, California, as well. As expected, it was found that the level was lower. Lettuce samples collected from this region at the same time as the soil samples showed 0.0004 MPC; broccoli, 0.00025 MPC; green peas, 0.00134 MPC; alfalfa, 0.0021 MPC. These values all are much lower than those for the midwestern United States (shown in Table 2).

The rainfall data for Brawley are as follows: In 1955 the rainfall totaled 1.70 inches, 1.3 inches having occurred in January of that year and 9 months having had no registered rainfall at all. In 1953 the annual total rainfall was only a trace, this trace having occurred in February.

At Antofagasta, Chile, where it has never been known to rain, except possibly on one occasion, we find 0.02 mc/mi^2 of Sr^{90} in January, 1956, when the general deposition for this latitude was apparently a little over 2 mc/mi.^{2} In other words

about 1 per cent of the fallout expected was found, and 0.02 is hardly larger than the experimental error of measurement.

Annual rainfall = 2.57 inches

In Lima, Peru, the total fallout of Sr^{90} in January, 1956, was 0.7 mc/mi^2. The annual precipitation in Lima averages only 1.89 inches, though there is a considerable amount of ground fog and mist.

It seems clear from these results and the reasonableness of the mechanism of deposition advanced by Mr. Greenfield that there is valid reason to believe that world-wide fallout is small in the absence of precipitation. Also, it is clear from this mechanism that the fallout should not be strictly proportional to total rainfall. Frequent light rains or mists would be expected to be more efficient than occasional heavy rains. The importance of rain is only to be revealed by a study of desert areas and a careful investigation of the scavenging mechanism itself. This work may well prove to be of considerable importance in meteorology, as well as in fallout studies. One should note that the local fallout due to larger particles which descend in the first hours probably does not need rain to precipitate it and occurs in the absence of the precipitation of moisture, although rain may well be able to increase even this fallout.

* Exchangeable Ca by isotopic exchange method for this sample was 19.0 gm/ft².

The importance of precipitation as a scavenging mechanism raises the possibility that different regions will be subjected to varying intensities of fallout, depending upon the weather conditions. It will be important to test whether this is so and whether it is a major effect in populated areas. We have evidence showing that extreme aridity greatly reduces the long-range or world-wide fallout, as explained above. The evidence to date does not indicate that it is a major effect for normal climates, in the sense that it does not appear to amount to more than a factor of 2. Regions in which people live normally have enough precipitation so that differences in precipitation appear not to affect the fallout by more than such a factor. Careful study of the data appended and the previously released data[2, 4, 5]

have failed to reveal any more serious deviation. To summarize, desert regions with little or no precipitation, or with only very minimum precipitation, apparently have minimum long-range, world-wide fallout; but other regions do not show that the fallout is proportional to the total precipitation, nor should it be expected to be so; however, detailed conditions related to frequency of precipitation might well be important. The data to date do not reveal deviations from the general average by more than about a factor of 2, and, in fact, they seem to indicate a smaller deviation than this. There is some evidence that certain areas have had more fallout than one might expect on the model described above and on previous occasions. In particular, there are reports that certain areas in England show higher levels, but the deviations appear to be considerably less than twofold.

More important, probably, than the variations in total fallout due to weather conditions is the effect of calcium in the soil in reducing the rate of assimilation of radioactive strontium by plants. The plants assimilate strontium because it is chemically similar to calcium and, since their appetite for calcium is limited, a larger calcium content in the soil dilutes the strontium so that a smaller fraction is assimilated. This effect might amount to a factor of 5 in the human-body assimilation of radiostrontium in regions with very low calcium content in the top soil.

C. *Direct Measurement of the Stratospheric Fallout Content.*—Direct measurement by means of high-flying balloons has shown that the stratosphere does indeed have about the fallout anticipated in it.[6] In addition, it has been found in these measurements that the radiocesium, Cs^{137}, occurs at about the same level as Sr^{90} in millicurie units, indicating that there has been no serious fractionation of the two fission products by the fallout mechanism. It further points out that the sampling of the stratosphere is a practical matter and that measurements can be made of the stratospheric content of radioactive fallout. Such data should greatly assist the whole study of fallout.

D. *Radiocesium Assays for the Biosphere.*—Recently a technique for measuring Cs^{137} in biosphere samples, particularly in human bodies, has been developed by Mr. L. D. Marinelli, of the Argonne National Laboratory.[7] It has been found that about four-millionths of one millicurie is present in an average adult. This corresponds rather well to the expected amount, considering the short residence time of radiocesium in the body, which is about 3 months, and the expected precipitation rate, which is taken to be equal, as a first approximation, to that of radiostrontium. The radiocesium, of course, constitutes no hazard, amounting in radiation dosage to a small fraction of the amount present in the blood in the form of that received from the ordinary potassium present in the body. Potassium is naturally radioactive. It is interesting further evidence, however, that the general model of fallout set forth is consistent with the data and essentially correct.

III. PLANS

It is clear that the peoples of the world are extremely interested in radioactive fallout because of the bearing that the new phenomenology of the nuclear age has on everyone's life. For this reason we must understand radioactive fallout in all its intricacies. It is to be hoped that the study will be a co-operative, international one. The United Nations Scientific Committee on Effects of Atomic Radiation offers an ideal forum for the discussion and consideration of the problem. From

these deliberations will come further suggestions, ideas, appraisals, and statement of the problem. The methods developed in this country for measurement and all the data collected are available to everyone. It is our hope and intention that this problem, like others of the atomic age, will come to be generally understood.

Fallout is normally considered an aspect of atomic warfare and nuclear armament. There is some similarity, however, between the weapons fallout and the hazard from a reactor accident, in which radioactive products would be disseminated over a limited area but would never reach the stratosphere or undergo anything like the world-wide tropospheric dissemination. As it has so often been observed in the past, so it is again true in this instance, that a new fact of nature is likely to have its beneficent as well as its somber and frightening aspects. As we learn about the way the world-wide fallout particle, probably as tiny as a virus molecule, wends its way from the stratosphere through the tropopause into the troposphere and, within a few weeks, collides with a water droplet and thus is brought to the earth's surface by rain, we shall learn more about the circulation of the atmosphere, about the way in which rain is formed, and about the questions which will naturally arise more and more frequently as the world's population increases world-wide pollution of the atmosphere not only with fission products but with the other by-products of our new technological age.

ISOTOPES IN METEOROLOGY

Remarks Prepared by Dr. Willard F. Libby, Commissioner United States Atomic Energy Commission, for delivery before the American Meteorological Society Chicago, Ill., Wednesday, March 20, 1957

A. STRATOSPHERIC MIXING

The existence of winds in the stratosphere together with the long residence times for fine particulates revealed by the fallout studies, make it seem possible that worldwide mixing may occur in the stratosphere in contrast to the troposphere. To establish or disprove this conclusion definitely and to measure the mixing rates would be possible with various radioactive isotopic tracers. The most immediately available are the bomb fallout products, in particular Sr90 and Cs137. This program is underway as Project Sunshine principally, with fallout collections being made by soil sampling and open pots at various places in both hemispheres as well as by means of a program of direct stratospheric sampling with air filters. From this work our present indications are that stratospheric mixing occurs in one or two years and that the over-all storage times for both Sr90 and Cs137 are both about ten years.

These conclusions will either become firmer or else be replaced by a more complicated mechanism corresponding to incomplete stratospheric mixing as Project Sunshine proceeds into its fifth year, and we probably will not be too optimistic if we expect that this study will definitely establish the mixing rate (and possibly the pattern), the storage time, and the general applicability of the single residence time to all stratospheric components which are not subject to commanding and dominating gravity fall. In other words, Sunshine may well teach us whether the whole concept of rapid stratospheric mixing relative to rates of removal into the troposphere is valid and whether these removal rates are the same for gases and particulate matter too fine to fall at any important rate, i. e., below 1 micron. This program will be prosecuted because of its commanding importance for fallout and meteorologists can expect that the help they may get may be appreciable.

It probably would be well to anticipate certain of these results so as to begin planning future experiments on this basis. For example, certain samples can be collected during the International Geophysical Year which would be important if the tentative conclusions that the stratospheric storage time is about ten years and the stratospheric mixing is essentially complete in two years, and that both apply generally to non-falling constituents, all are correct.

There are various types of particulate substances which may originate in the stratosphere and which should, therefore, be constantly fed into rainfall by the slow stratospheric feeding mechanism, whatever it be. Among these is meteoric dust. The fine meteoric matter which is too small to fall by gravity, i. e., O.1 micron or smaller, should blow about in the stratosphere establishing a more or less uniform concentration and finally descend through the tropopause and be precipitated by rain just as in the case of radioactive fallout. It might be wise to take filter samples of stratospheric air to establish the concentration of this material and if some technique for distinguishing this dust from ordinary dust can be devised, it would be interesting to establish the concentration in ordinary rain. It seems likely that the amount is adequate for detection in view of the quantities of meteoric material found in deep sea sediments.

Another type of material which may be descending from the stratosphere is the dust thrown into the stratosphere by megaton sized nuclear explosions. This material probably can be distinguished from meteoric dust by its chemical properties. For example, material from the South Pacific is mainly either calcium carbonate, calcium hydroxide, or sodium chloride, the various solid substances other than ice and, of course, the bomb materials themselves which are derivable from the surface material which could contribute to the fireballs.

It has been suggested recently by Dr. Philip Abelson that the type of mechanism described by Professor Urey and Dr. Stanley Miller might generate amino acids in the atmosphere by the photochemical action of the ultraviolet light from the sun in generating free radicals which could react to form these all important molecules. If this be true, it may be that rain contains amino acids from this source. It, of course, will be difficult to distinguish these molecules from earth dust and the amino acids from the ordinary living material. It may be possible to do this by using the fact that the ordinary amino acids are optically active whereas the postulated stratospheric materials presumably

would not be and thus could be distinguished in principal, at least. Of course, direct stratospheric samples should reveal these materials in much less contaminated form so if search in rain samples fails to reveal them stratospheric air samples may.

Natural tritium produced by the cosmic rays, or, as recently suggested by Dr. Arnold and Dr. Feld, possibly assimilated directly from the sun, is naturally produced or acquired at the highest rates in the highest layers of the stratosphere. The cosmic ray primary radiations interact with a mean free path of about 1/10 of the atmosphere, so although there is appreciable probability of production below the tropopause, the main part of the cosmic ray interactions with the aid occurs in the stratosphere. Since it is extremely likely that tritium, being an isotope of hydrogen, will burn to water, we essentially have a source of radioactive water in the stratosphere. The recent results from fallout suggesting that the stratospheric storage time for fine particulate matter is of the order of ten years, make it appear likely that a considerable fraction of all the natural tritium resides in the stratosphere, and that, in fact, it may spend a considerable part of its average radioactive life of 18 years there and so disintegrate there in considerable degree to form He^3 before entering the troposphere and the earth's water system. The ratio of the moisture content of the stratosphere to that of the troposphere is so small that if taken together with the stratospheric storage factor mentioned, it leads one to expect that the tritium concentration of stratospheric moisture may well be as much as 100,000-fold above that for ordinary surface water. This ratio of the stratospheric concentration to the tropospheric concentration will, in itself, give a more or less direct measure of the storage time. The sampling of the stratosphere for moisture must, of course, be done with balloons, aircraft or rockets, and air filters which will collect the moisture. It is not necessary apparently to know the volume of the air which is sampled, so the problem is one of the simplest of the stratospheric sampling problems, and it seems that it should be relatively simple to do. It would be important to sample at various latitudes to determine whether the expected uniformity with respect to latitude actually exists. It also would be very valuable to have data versus altitude.

Perhaps a word should be said about the short residence time of the bomb tritium in the stratosphere. Why is it possible that natural tritium have a residence time of perhaps ten years in the stratosphere whereas at least a major part of the bomb tritium, which certainly was pushed into the stratosphere with the bomb cloud, was observed by Dr. Begemann and myself to spend only something like 40 days in the atmosphere? The reason probably is that the bomb tritium is contained in relatively large ice crystals. The amount of water in the fireball is so large that when the fireball is pushed into the stratophere and cooled, relatively large ice crystals form. The proof of this lies in the appearance of the cloud, for the cloud as actually seen in its white mushroom outline in the stratosphere is visible mainly because of ice crystals or supercooled water droplets. In any case, the material which is pushed into the stratosphere is of sufficient mass so that gravity fall will cause it to leave the stratosphere relatively quickly. It is the material which does not settle by gravity that we expect has the ten year residence time. Probably any bomb fired in the troposphere will have enough moisture from the air so that it will form large enough ice crystals to cause the tritium to fall out relatively quickly. The stratospheric water samples need not amount to more than a few grams for the concentration should be high enough so isotopic enrichment would not be required. I am sure that Dr. Begemann would be pleased to measure these samples if anyone can obtain them. We will make efforts on our own part, but it is our hope that flights being made for other purposes can be used to obtain these moisture samples.

B. TROPOSPHERIC MIXING

In contrast to the stratosphere, the tropospheric residence times for particulate matter seem to be relatively short. Work with radon decay products done by Haxel in Germany and by Blifford and Damen and other people in this country, all agree that whatever the fate of the non-volatile radioactive decay products of the four day half-life radioactive noble gas radon emitted by uranium, the materials stay in the atmosphere only a fwe days before being precipitated out, probably mainly with water droplets. This is the same story as for the fallout particles. All the evidence known apparently indicates that there is some type of mechanism by which troposheric air is periodically cleansed in a matter of a few days, or at most a month or so.

It has been known for a long time that the rain and snow are good scavengers for atmospheric contaminants, and the clearing of the atmosphere following precipitation is recognized by everyone as a fact. It is less well known that this holds true even for the finest material. The new evidence for this is that the fine material which resides in the stratosphere for periods of years is, in fact, carried down by water droplets when it enters the troposphere in a relatively short time. This agrees with the radon decay products evidence for it was shown by Werkman and his coworkers that the particles which collect the radon decay products are in general microscopic, probably of the order of a few hundred angstroms in diameter. What can this mechanism be?

It is very well known that a falling raindrop can hardly pick up any particle so small that its inertia will not prevent its flowing around the raindrop as the air molecules do. Therefore, it has been something of a mystery as to how the fine particulate matter which carries the world-wide fallout in the stratosphere could be precipitated in the form of rain, as was shown rather conclusively to be the case by the fact that fallout is observed to be minimal in desert regions (though it is by no means proportional to total rainfall in other areas). The answer seems to have been given by Dr. Stanley Greenfield, who pointed out that the Brownian motion, that is, the violent random motion due to collisions with the air colecules, gives these tiny particles a considerable probability of colliding with the droplets in clouds. Therefore, he suggests that any cloud, mist or dew is an excellent medium for scavenging fine particulate matter and placing it, of course, in the rain which is formed subsequently from clouds. From this theory, which seems to be so explanatory of much of the information on moisture scavenging of fine particulate matter, we would expect that the efficiency with which fine particles entering the troposphere from the stratosphere are carried down will depend not so much on the total rainfall or total moisture precipitated as on the average lifetime of a particle as determined by the probability of its colliding with a smaller water droplet in a cloud, mist or fog. In other words, a foggy climate, or one given to morning dews, or one with frequent light rains, may well be more effective in this precipitation mechanism than one with infrequent heavy rains. The fallout evidence seems to agree with this, but further work with the Greenfield theory in mind ought to establish the matter clearly.

Of considerable more importance for meteorology, it seems likely that nucleation nuclei will in themselves have the same fate that these fine particles we speak of suffer, and that the fallout pattern should be the pattern for the cleansing of the air of stratospheric nucleation nuclei which are so important in the formation of ice crystals. The study of this problem of the history of fine particulate matter in the troposphere ought to be of real value to meteorology.

Thus, we have a model for the complete removal of particulate matter from the troposphere by water drops since the mixing up to the tropopause seems to occur in a matter of weeks, and this residence time for the particulate matter appears to be about the same as the residence time for the average water molecule in the troposphere. It appears that the air in the bottom rain-bearing layer of the troposphere is cleared in about 1 week while the troposphere as a whole requires 3 weeks or a month on the average.

Of course, these results are incomplete and it is necessary that many of the features be tested by further experimentation. For example, we should find whether it is really true that the air in a cloud is clear of fallout, and that the air in a fog is free of condensing nuclei and of virus molecules and all other forms of particulate matter which are fine enough for the Greenfield mechanism to operate. Some of these experiments could well be conducted in the course of the International Geophysical Year.

In contrast to the stratosphere, it seems that the short residence time in the troposphere makes latitudinal mixing essentially impossible. Thus, we find that fallout which never reaches the stratosphere or which falls out of the stratosphere quickly does not spread itself across the equator latitudinally. Most of the fallout from the testing in the Northern Hemisphere being tropospheric in character has occurred in the same general ranges of latitudes as the test sites occupy, and to a rough approximation it is true that all of the fallout in the Southern Hemisphere is due to stratospheric material disseminated by the stratospheric mixing mechanism. Therefore, it should consist of radioactivities which are necessarily old and, therefore, should not contain short-lived radioactive fission products because of the long stratospheric residence time. This point needs experimental testing. It is not a difficult measurement and the results should be available soon.

Insofar as these conclusions and predictions are borne out by further observation, we can expect that particulate contamination of the tropospheric air by industrial sources and others will restrict itself largely to the general region of the heavily populated areas in the Northern Hemisphere, and that any effects of such sources of particulate matter on the local weather should not pass themselves across the equator. It would be extremely interesting to observe whether the density of nucleation nuclei for ice crystal formation is appreciably lower in the Southern Hemisphere, as it might be according to the above notions.

C. MIXING OF THE STRATOSPHERE WITH THE TROPOSPHERE

The mechanism by which stratospheric material eventually finds its way into the troposphere can be elucidated in part by the use of isotopes. For example, if the stratospheric residence time for fine particulate matter and gaseous materials should prove to be identical there would be no doubt any longer that the mixing is one of air masses rather than the falling out of particles or the removal of fine material by some other mechanism. We might for a moment consider a specific mechanism for the removal of matter from the stratosphere into the troposphere and vice versa—a mechanism which consists of a mixing caused by or associated with the seasonal change in the height of the tropopause. This rise and fall of the dividing layer between the troposphere and stratosphere will constitute a type of pumping action. The shifting of the boundary occurs periodically and while the tropopause is near its higher levels, the characteristic rapid mixing of the troposphere takes the air which was formerly in the lower layers of the stratosphere and mixes with what was formerly in the troposphere; and during the subsequent time when the tropopause is at its lowest level, tropospheric air will be mixed similarly with the stratosphere. Now if the oscillation is assumed to occur annually and perhaps one-tenth or one-twentieth of the atmosphere lies between the two extreme locations of the tropopause, it would appear that ten to twenty years would be the expected average time for mixing. This is so reasonable in terms of fallout observation that it may just be that this relatively simple mechanism is the correct one. It was first mentioned to me by Professor James Arnold of Princeton University, but I am sure that meteorologists have thought about it for a long time. This model would predict that the mixing does not occur at exactly the same rate at all points on the earth's surface and the longer residence time in the stratosphere and the magnitude of the stratopheric winds would have to be depended upon to accomplish the latitudinal mixing.

Assuming this mechanism, one could say that the noble gases would establish a steady concentration in the atmosphere which in the case of radioactive materials would be determined by their radioactive half-life and the mixing time, since rain and water cannot scavenge and precipitate them. There is evidence for this already in the case of radon. The ratio of the abundance in the stratosphere to the abundance in the troposphere of the radioactive noble gas radon which has its origin at the earth's surface is known to be essentially zero. By the time the radon can be transported into the stratosphere there is litle if any left because of the four-day half-life for the radioactive decay. Air filters in the stratosphere show little radon decay products. This fact shows that the general model has some applicability to gases.

Gases generated in the stratosphere such as molecular hydrogen containing tritium should establish a concentration ratio between the stratosphere and troposphere which would be determined again by the stratospheric residence time and the radioactive half-life. If, for example, we assume that tritium is generated only in the stratosphere and that the molecular hydrogen has a negligible rate of combustion to water after being formed (an experimental fact in the laboratory unless a spark occurs); one calculates that the ratio of the tritium concentration in the form of molecular hydrogen in tropospheric air to that in the stratosphere should be slightly less than one-half, the half-life for the radiotactive decay of tritium being 12.26 years. This calculation also assumes that the escape of molecular hydrogen from the atmosphere into interplanetary space occurs at a rate which is negligible compared to the rates of combustion and the rates of mixing with the tropospheric air.

A check can be made on the assumption that the rate of combustion of molecular hydrogen in the stratosphere is small compared to the rate of mixing with the tropesphere by observing the ratio of the concentration of molecular hydrogen in the stratospheric air to that in the troposphere. This is so because

it is probably a valid assumption that molecular hydrogen is generated solely in the stratosphere by the action on water vapor of the ultraviolet radiations from the sun. If the combustion lifetime is long compared to the general stratospheric residence time for stratospheric matter, the compositions in the two layers will be the same. This observation would be important to make. It would require the collection of considerable amounts of stratospheric air in order that the hydrogen content could be determined. Similar analyses have been made on the noble gas content of air as a function of altitude.

D. SUMMARY

In conclusion, it seems likely that isotopes can contribute appreciably to meteorology both in the new techniques and data they can furnish as well as in interesting students of other disciplines in the problems of meteorology. Meteorology is such a broad subject that the possibilities for applications of specialized techniques and knowledge are large, ranging all the way from biology to pure astrophysics.

Isotopes have been observed many times to have a catalytic effect in encouraging the mixing of disciplines in science. Physicists and chemists have intermingled for years in the pursuit of nuclear science and the long history of biology is remarkable for the important contributions made by men from other disciplines. If isotopes can help catalyze this intermingling, this service alone will in itself constitute a considerable contribution to meteorology.

We have made only brief references this evening to the cosmic ray radioactivities. The reason is that these have been discussed previously in considerable detail by others, but we should not leave the subject without referring to the fact that in addition to radiocarbon and tritium, two beryllium isotopes and a chlorine, a sulfur, and two phosphorous isotopes all have been reported to be produced by the cosmic rays as they bombard the atmosphere. These give additional opportunities for meteorological observation similar in kind to those discussed in some detail tonight.

There are many other potential applications of isotopes. The possibilities of artificial labeling of air masses by the use of radioactive isotopes are important, and the maximum information has not yet been obtained from fallout material. So many other possibilities exist that meteorologists should earnestly consider the applications of nuclear techniques to their field. In many instances they will find the Atomic Energy Commission very interested in the research.

Remarks prepared by Dr. Willard F. Libby, Commissioner, United States Atomic Energy Commission, for delivery before the University of New Hampshire Distinguished Lecture Series, Durham, N. H., April 11, 1957

Radioactive Fallout From Nuclear Tests

FALLOUT FROM TESTS

There is a great deal we do not know about the precise effect of radiation on the human body, but we do know that the effect of radioactive fallout from nuclear tests is not, nor is it likely ever to be, the danger to the human race in this generation or in later generations which many people have been led to believe.

Long before nuclear weapons were even thought of, in fact, ever since people have lived on this planet, they have been subject to radiation from cosmic rays and from the radioactive material in the crust of the earth. In recent years has been added radiation from the use of X-rays, from luminous devices, etc.

Let us compare radiation from test fallout with radiation from some of the other sources which have been with us through all times so that we may better evaluate fallout as an element of danger. Cosmic rays, which come from outer space, have their radiation effect progressively diluted as they pass through the atmosphere surrounding the earth. Thus, the person living in Denver, Colorado, at an altitude of about 5,000 feet receives a dosage of cosmic rays approaching double that of a person who lives at sea level.

At the present time, the radiation dosage to bone from the most worrysome part of radioactive fallout, which is Strontium-90, is about the same as what

the Denver resident would receive as additional radiation from cosmic rays if he moved from Denver proper about 200 feet up on the mountainside, or to the resident at sea level if he moved from the beach to the top of a hill 300 feet high.

More exactly, and using the measure commonly used for radiation exposure, the roentgen, which is an amount equal in the chest to six to 10 chest X-rays—at sea level in our latitudes we receive 37 thousandths of one roentgen each year from cosmic rays, while people living at Denver, Colorado, at an altitude of 5,000 feet receive 60 thousandths of a roentgen annually. Now, in order to compare fallout we must put all items in the same terms.

FALLOUT AND RADIOACTIVE STRONTIUM

At the present time, the radiation effect on human bones from radioactive strontium, the most worrisome part of radioactive fallout, is about 1.5 thousandths of a roentgen annually—about one-fifteenth of the difference between the cosmic ray dosages at sea level, and at 5,000 feet elevation, or equal to the extra cosmic rays at the extra height of about three hundred feet.

Radioactive strontium does not occur naturally but is produced by nuclear reactions. It also has a natural tendency to stay in our bones and thus to irradiate them. How much does it amount to? As just stated, the most recent data show that children in the United States have about 1.5 thousandths of a roentgen annually of extra bone exposure from the radiation from radioactive strontium. Adults have much less because their bones grow more slowly. This country has somewhat higher rates than elsewhere because of our tests in Nevada.

The effects of irradiation of bone are bone tumor and leukemia. How much hazard does the bomb test radioactive strontium constitute? This is a difficult question to answer with complete certainty for the amounts which cause these effects are not well known, but we do know that the dosage is much less than the extra cosmic ray dosage at 5,000 feet altitude as compared to sea level. We have examined the vital statistics on these dread illnesses to see whether there is a higher rate for populations living at 5,000 feet than for those living at sea level in order to get from these data some direct notion about the magnitude of the effect. There is no evidence of any observable effect of the extra radiation in these numbers. The average annual incidence of bone cancer at both levels was about 2.8 per 100,000 people in 1947, and for leukemia, the average was about 7. The actual numbers were:

Occurrence of bone cancer and leukemia

[New cases per year per 100,000 population]

	Bone cancer	Leukemia
Denver	2.4	6.4
New Orleans	2.8	6.9
San Francisco	2.9	10.3

Figures obtained from National Institutes of Health, Department of Health, Education, and Welfare.

Since excessive doses of radioactive strontium are known with certainty to cause both bone cancer and leukemia in animals, we must not deprecate or casually dismiss the possible results of a widespread, but low intensity, effect in causing these disabilities. However, by using normal experience insofar as it is applicable, we can orient ourselves with respect to this new factor in our environment—much as we do for other results of our modern way of life. We cannot see any effect of a radiation dosage fifteen times the present test fallout dosage in large populations, but the number of cases of bone cancer and leukemia each year, even in the large cities, is small so our data may not be too significant. However, these figures do point to a definite tangible evidence of a margin of safety.

Perhaps more pertinent, though less direct, is the result of animal experimentation and the rare human experience on the effects of radiation in causing bone tumors and leukemia. The official tolerance limit for people working in atomic energy plants and with radioactivity professionally is 2,000 times the present bone content for children in the United States, and about 10,000 times that in

adults. However, it has been recommended by high scientific authorities that the tolerable amounts of radioactive strontium for the population in general should be only one-tenth of those acceptable for workers who of course expose themselves voluntarily. On this basis the present level in children is 1/200 and, in adults, about 1/1000 of this maximum permissible concentration for large groups of people. Perhaps a word of explanation of these tolerance or maximum permissible concentration limits would be helpful. When scientists speak of "risk" or "hazard," they do not use the words in the same sense that most laymen regard them. Scientists try to be precise; they measure such things almost to the limits of the finite; therefore, "risk" means possible effects far beyond the range of the probable or detectable. The maximum permissible limits do not mean that above those limits one encounters trouble—but rather that perhaps only a ten-fold larger concentration would give effects which would be definitely detectable.

WHAT ABOUT THE FALLOUT STILL IN THE STRATOSPHERE?

If all the radioactive fallout which still is airborne should come down suddenly, there would be about one-third more total radioactive strontium on the ground than we now have here in the United States. It falls so slowly, however, that there is expected to be relatively little increase over the present amount deposited—the extra fallout just about compensating for the naural radioactive decay of the radiostrontium already deposited. (The radioactive decay occurs at the rate of 50 percent every 28 years.) The ground level will remain about constant for the next ten years and then drop off at the rate of about 2.5 percent per year due to radioactive decay uncompensated by further fallout from the upper atmosphere. Therefore, in the United States the present level is about as much as we shall ever have from tests already fired.

WHAT ABOUT POSSIBLE GENETIC EFFECTS?

Radiostrontium is not the only fallout product of nuclear bombs. In fact, there are dozens of others but, for one reason or another, these fail to accumulate inside the body as radiostrontium does. However, certain of these other fallout materials do emit penetrating radiation which can irradiate the body from the outside and thus possibly can have effects on the health and can produce genetic mutations. In fact, for early fresh fallout close to the site of a nuclear explosion, this radiation of the body from the outside is the principal hazard, and it is only later on that radiostrontium becomes important. There is one short-lived form of radioactive iodine which is assimilated into the thyroid gland so it is not quite correct to say that no internal irradiation occurs from early fallout, but the external radiation certainly is the main hazard with which the United States Government is concerned in planning protection against enemy nuclear bombs. Later on and far away from the test site, months and years afterwards, there still is some external radiation which does amount to a detectable total and it is this radiation which raises questions.

We are continually being bombarded by radiations not only from the cosmic rays from outer space—the cosmic rays mentioned above—but from the earth and even from our own bodies. Following our previous tactic of comparing these new fallout effects with normal experience insofar as it is justified, we now compare these external radiation exposures with those normally encountered. The external radiation doses from test fallout have averaged between 1 and 5 thousandths of one roentgen per year during the last three or four years. Now, this is to be compared with a normal dosage from ourselves and our environment of 150 thousandths of a roentgen per year. Therefore, we conclude that the radiation dose from test fallout is relatively very small, but the question remains: "Small as it is, does it have genetic and health effects?"

The direct experience which we have had on health effects is reassuring. We do not see that the much larger dosages received by people living in the higher altitudes or in localities which are particularly radioactive have had noticeably bad effects—the effects expected are cancer and shortening of life. However, it may be that small effects do occur which because of their smallness are difficult to see. The only definite thing we can be certain of is that test fallout is very small as compared to natural dosages and, therefore, we know that the effects must not be very far outside of normal experience. One environment can differ from another in natural radiation intensity by much more than the total fallout. For example, a brick or concrete house can easily have enough natural radioactive material in the walls to give up to 40 thousandths of a roentgen per year more exposure than a wooden house—this is between 8 and 40 times the

annual dosage from test fallout. The genetic effects are much more difficult to consider since they will show up only in later generations and, most importantly, only when both parents have been affected either directly or through affected parents. But by study of animals and plants we know that radiation does produce genetic changes—we even irradiate plant seeds in order to speed up the rate at which new forms appear so superior new plants can be produced by selection of the few desirable ones and cultivating them in the way Luther Burbank developed so many useful new plants using just those naturally occurring forms. However, most of the forms from the irradiated seeds have inferior properties and it is only a rare one that is a definite improvement on the original plant. Similar results are found with animals so we guess that human beings probably are subject to same type of effects. Therefore, we believe that there must be *some* genetic effects of test fallout radiation but, again, from our normal experience in which no effects of high altitudes versus low, or brick versus wooden houses, etc., have been observed, we know that the effect must be very small. The laboratory experiments on plants and animals agree with this, but do insist that there must be some very small effect, although it will be entirely undetectable from test fallout.

WHAT ABOUT FUTURE TESTS?

Continued testing at the same rate and in the same way as during the last five years will not increase the hazard on a straight additive basis since an equilibrium will be established between additions of radioactivity and radioactive decay. For Strontium-90, the maximum factor of increase possible is eight-fold and the external radiation exposure outside the immediate test area would behave similarly. In 1980 it would be four times the present and, in 2011, about six times, and so on until after a very long time it would approach the factor of eight.

The cause for real concern is not the deleterious effect of radiation resulting from weapons tests, but rather what would be the effect of the infinitely greater amount of radiation which would result from the massive use of nuclear weapons in warfare. Here we would be dealing with excessive radiation, not to all the people of the world as has been suggested, but quite probably to large numbers of people residing in areas of substantial contamination. With regard to the people so overexposed, there would be serious increases in the pathological effect of excess radiation, such as cancer and leukemia. There would, also, be the genetic effect which would manifest itself in the children and the children's children of such people.

In nature, there are mutations in plants, in animals, in human beings. Some mutations show superior characteristics and these make it possible for us to develop superior strains, but unfortunately most mutations are harmful rather than beneficial. For this reason and because their effect is not limited to one generation, the genetic effects of excessive radiation may be more important than the pathological effects.

If radiation—from weapons test fallout, from natural sources, from the normal use of X-rays—is all measured in quantities so minute as to have very small effects on either present or future generations, we should concentrate our concern on what would happen if the world should engage in a nuclear war, for therein lies the real danger to mankind.

It is not contended that there is no risk, however minute. But all life, and every minute of our day and night, is measured in terms of risk—40,000 highway deaths each year in this country, accidents in the home, etc. We make our choice: How much risk are we willing to take as payment for our pleasures (swimming at the seashore, for example), our comfort or our material progress? Here our choice seems much clearer. Are we willing to take this very small and rigidly controlled risk, or would we prefer to run the risk of annihilation which might result if we surrendered the weapons which are so essential to our freedom and our actual survival.

RADIOACTIVE FALLOUT

Remarks prepared by Dr. Willard F. Libby, Commissioner, United States Atomic Energy Commission, for delivery before the spring meeting of the American Physical Society, Washington, D. C., April 26, 1957

I. INTRODUCTION

The radioactivity produced by the fission reaction changes its characteristics continuously and rapidly following the explosion of an atomic weapon and the

conditions of firing are of extreme importance in determining the rate at which the radioactivity descends to earth. As a result there are in general three different kinds of radioactive fallout, the relative importance of which is determined by the nature of the weapon, principally its yield, and the conditions of firing. These three types are: First, *the local fallout*, which is insignificant unless the fireball touches or comes close to the ground, but which in case the fireball does touch the ground can amount to a major fraction, in some instances as much as 80 percent of the total debris. This type of fallout consists of radioactivity which is carried down by the larger particles. It consists largely of matter drawn up into the fireball from the surface which is either totally or partially vaporized. Under these conditions so much matter is vaporized by virtue of the fireball's touching the ground that the particle sizes formed in the freshly cooled vapor are large.

The second and third types of radioactive fallout are world-wide in nature and consist of finer material and are divided according to whether the material happens to lie in the lower part of the atmosphere, the troposphere, where rain and weather phenomena occur, or the higher part of the atmosphere, the stratosphere, which is free of such precipitating mechanisms. The *tropospheric fallout* occurs in a matter of two or three weeks or a month or so. It occurs largely as a result of rain and snow, and water precipitation in general, and falls in the general latitude of the test site. The *stratospheric fallout*, in contrast, takes years. We are not completely certain, but it appears that an average time of something like ten years, or perhaps somewhat less, is a reasonable figure, and during this time the distribution becomes nearly world-wide. When the stratospheric fallout manages finally to pass into the troposphere it is quickly removed by the same type of mechanism that brings down the world-wide tropospheric fallout, namely rain and moisture.

The precipitating mechanisms consist in general of the collision of the tiny particles with moisture droplets in clouds, together with the interception of particles by falling raindrops. The first mechanism was recently suggested by Dr. Greenfield in connection with Sunshine problems—the study of world-wide fallout is called Project Sunshine. In addition to the scavenging action of rains and fogs, there is definite evidence for a considerable probability of pick-up on direct contact of air with surfaces such as the leaves of grass and trees. Frequently, grasses are found to have higher strontium-90 content than would correspond to the soils in which they grow, and this is due undoubtedly to direct pick-up.

The dissemination of strontium-90 and all fallout is greatly dependent upon the firing conditions. There is every evidence that important factors include not only contact of the fireball with the surface, but the nature of the surface, whether it be land or water and the type of soil and the composition of the water, whether fresh or sea water. Also, the height to which the fireball rises is important, in particular the height relative to the tropopause, the dividing layer between the troposphere and the stratosphere. Yield is the main consideration here. A rough rule is that megaton weapons push through the tropopause into the stratosphere, and kiloton weapons stay below the tropopause in the troposphere.

Thus, we see immediately that kiloton weapons deposit their fission products much more quickly than do megaton weapons. Of course this is of less importance in so far as the long-lived fission products, such as strontium–90 and cesium–137, are concerned, but it is of more importance for the shorter-lived fission products. As a general rule, an air-fired kiloton weapon will deposit its radioactive fallout in a period of between two weeks and one month on the average after the detonation, whereas an air-fired megaton weapon will deposit its radioactive fallout over many years—on the average about ten years. Thus, the effects which are due to the short-lived fission products are larger for a given amount of fission energy release in kiloton weapons than they are for air-fired megaton weapons. Considering the average age of the kiloton fission products to be 1 month, the external gamma ray exposure from one megaton of fission fired as say 50 bombs of 20 kilotons each would be 30 times that for a single bomb giving one megaton of fission energy—if both were fired well up in the air. The fission products from the small bombs fired in Nevada would fall in the latitudes 10°N to 60°N in about one month, while the larger bomb

would give fallout over essentially the whole earth in about 10 years. For strontium-90 effects there is relatively little difference per unit fission yield since even to the residence time in the stratosphere is small compared to the 28 year half-life of radioactive strontium and the 27 year half-life of radioactive cesium, which is produced at slightly higher yield than strontium-90, and which appears to be disseminated in about the same way.

The content of radiostrontium and radiocesium in the stratosphere is by direct measurement shown to be roughly the same though the radiocesium is somewhat higher possibly due to the slightly higher fission yield. The content of radiocesium in rainwater is comparable to that of strontium-90. Also, the content of radiocesium in the human body as measured by Marinelli at Argonne and Anderson and Langham at Los Alamos agrees well with the fact that it has an average residence time in the human body of about five months as compared to many years for strontium-90. The radiocesium data are very interesting because of their bearing on the fallout dissemination mechanism and the confidence with which we can establish the probable future behavior of radioactive strontium. The data confirm previous suggestions as to the dissemination mechanism, that is, we find that radiocesium fallout except of the local variety is carried down very largely in the form of moisture droplets and that there is some direct pick-up by leaves and grass on surfaces. It is captured and held tightly by the top two inches of most soils, so the water which falls and runs off in the form of rivers is clean by the time it has drained a short distance through soil. All of this is very similar to the radiostrontium behavior.

The plants pick the strontium-90, and radiocesium to a lesser extent, out of the soil and also off of their leaves and take it into their systems. There appears to be a discrimination mechanism which operates in most plants so that the strontium-90 content of the plant is considerably less relative to its calicum content than in the case of the soil. On the average, the discrimination factor between the top soil and plants against strontium relative to calcium seems to be about 1.4. When the cows eat grass they further discriminate by about a factor of 7 in making milk so there is an overall protection factor for strontium-90 from the top soil to milk of about 1.4×7 or 10. Also, there is a further discrimination factor against strontium relative to calcium in the human body. This factor is not known too well, but is known definitely to be at least as large as 2 and is thought possibly to be as high as 8. Researches are now in progress to settle this. Therefore, there is a series of protective factors which makes the concentration of radiostrontium derived from milk relative to calcium in human bone not over 1/20 and possibly as little as 1/80 of that in the top soil. Of course, it should be pointed out that there is a considerable part of the fallout which is picked up directly on the leaves and to this the factor of 1.4 does not apply, so for this fraction of the fallout the protective factor may be reduced to 14. Since milk is the source of most of our calcium, this means that the actual ratio of radiostrontium concentration in new human bones relative to that in the top soil should approach these numbers.

It must be realized that though only a small part of the calicum is derived from vegetables and meat, a similar calculation must be made for this portion and the total average ratio obtained. It seems that the meat-vegetable overall discrimination factor is about 10 so if 20 percent of the calcium is derived from such sources on the average the average overall factor will be between 1/13 and 1/30. The experimental data on new human bone in children appear to give a smaller figure, 1/60, as mentioned later.

A matter of importance in connection with the amount of strontium-90 which one would expect to be deposited in human bone as a result of atomic weapon detonation is the calcium concentration in the top soil. Since calcium is so similar to strontium, it seems very likely, and the evidence confirms this, that high available calcium content of the soil will reduce the probability of strontium-90 being taken up into the plants. Of course this probably does not have nearly as great an effect on the uptake of the material which is picked up directly on the leaves. We might expect therefore that soils which are particularly low in calicum might show higher strontium-90 contents for the grasses grown on them. This is, in fact, so, and sheep and goats and cattle feeding on such pasture display a higher strontium-90 bone content.

How such calcium deficiencies in the soil should affect the strontium-90 uptake by the human population is a most important question. One sees immediately that food distribution systems are such that the food supply is derived from large areas, and that there is consequently a sharp reduction in the sensitivity of the

human population to calcium deficiencies in local soils. This is brought out particularly well by the data on the radium contents of human bones and their obvious lack of strong dependence on the radium contents of local waters. But for people who consistently drink milk from cows grazing on such ground there should be a definite effect on the amount of radio-strontium uptake and the effect should be proportional to the radiostrontium content of the milk. So the question resolves itself largely into "What are the strontium-90 contents of the foods people in such regions actually consume?" We find on inspection of the food eating habits and calculation of the strontium-90 intake relative to calcium, that the increase in average strontium-90 concentration of the food due to the low calcium content of the particular soils can hardly be more than five-fold for a soil-calcium deficiency of 50-fold. That is, whereas normal soil carried about 20 grams of available calcium in the top 2.5 inches, a region with soil of only .4 grams per square foot would produce a human body burden equilibrium of about five times that which the normal soil would produce.

In order to understand the hazard of radiostrontium, which is generally agreed to be the most hazardous of the long-lived fission products, we try to establish the maximum permissible concentration both for occupational workers and for the population in general. These numbers have been set at 1 microcurie and .1 microcurie for the standard man, respectively. That is, an occupational worker may carry 1 microcurie of strontium-90 in his body, whereas the general public should not have over .1 of a microcurie of strontium-90 in the average standard adult. This last figure corresponds to a concentration of 100 micromicrocuries per gram of body calcium or what we call 100 Sunshine Units, that is, 1 micromicrocurie of strontium-90 per gram of body calcium is defined as 1 Sunshine Unit.

Now, we must try to see in some other way how our normal experiences can be brought to bear on the question: "How dangerous is atomic weapons testing from the pont of view of radioactive fallout?" At the present time we have in our bodies about .1 or .2 of a Sunshine Unit and children have about one-half of a Sunshine Unit. In a few minutes I will speak about the question of the variation from these average values, but assuming at the moment that these are the values, what is the threat or the hazard from these quantities? Obviously, they are much smaller than the 100 Sunshine Unit tolerance figure mentioned above. To obtain a comparison with normal experience, let us consider the fact that we know in a general way the magnitude of the radiation levels to which we are normally subjected by the cosmic rays, potassium in our own bodies, and the uranium, thorium and potassium in the ground and in our surroundings. We know these qantities amount to something like 150 milliroentgens per year for an average person in this latitude. But we also know that there are considerable variations with conditions.

For example, a person living in a brick house may very well get 25 to 50 milliroentgens per year more than one living in a wooden house, because of the natural radioactivity of the bricks. It is also very well known that whereas at sea level in this latitude the cosmic ray dosage is 37 milliroentgens per year, at 5,000 feet altitude as in Denver, Colorado, the dosage from cosmic rays is 60 milliroentgens per year, or a difference of 23 milliroentgens per year. What is this in terms of strontium-90 body burden?

First, we must consider what part of the natural radiation, if any, is similar to the radiation of strontium-90 in biological effect so we can say without doubt and hesitancy that the physiological effects, whatever they are, will be the same for the same energy absorbed. Fortunately, the cosmic rays seem to fit this bill. In other words, we are at liberty to compare the cosmic ray radiation dosages with the dosages from radiostrontium in our bone structure. The reason this is permissible is that the ionization density along the tracks of the mu-mesons which are the principal cosmic ray components at sea level and at altitudes of 5,000 feet are nearly the same as those of the yttrium-90 beta rays, the principal radiation which radiostrontium emits; that is, radiostrontium has a radioactive daughter, yttrium-90, which emits a very energetic beta ray and the ionization density along the track of this radiation is very similar to that of the mu-mesons of the cosmic rays and their disintegration electrons, and it is generally accepted by health physicists and radiobiologists that radiations of the same ionization density have very similar, if not identical biological effects for the same energy absorbed. The high energy of the yttrium-90 gives it an average distance of penetration in tissue of 2 millimeters so any effect of local non-uniformity of deposition of strontium-90 in the bone is removed. The cosmic ray exposure is, of course, uniform throughout the bone structure. Therefore, we can equate cosmic ray dosage

with strontium-90 dosage and thus it is possible for us to say that the difference between one altitude and another is equal in effect, other effects being equal, to a certain number of Sunshine Units in bone. Now to follow this thought through, 1 Sunshine Unit is equal to 3 milliroentgens per year. Therefore, the difference in annual cosmic ray radiation dosage between Washington, D. C., or any place at sea level in this latitude, and Denver, Colorado, is equal to 8 Sunshine Units, that is, 16 times the present body burden of equilibrium bone or bone near equilibrium as we see it in young children who are growing now.

Therefore, we must examine whether anything in our experience indicates that these differences are significant in terms of the occurrence of the principal effects expected of radiostrontium, namely leukemia and bone cancer. Now of course when one looks for such vital statistics, one finds that they are very hard to acquire. However, the National Institutes of Health and the Department of Health, Education and Welfare, have given us statistics for the occurrence of leukemia and bone cancer for the year 1947 for the three cities, New Orleans, San Francisco and Denver. They are shown in Table I.

TABLE I.—*Occurrence of bone cancer and leukemia*

[New cases per year per 100,000 population]

	Bone cancer	Leukemia
Denver	2.4	6.4
New Orleans	2.8	6.9
San Francisco	2.9	10.3

It is clear from this table there is no obvious effect of altitude, and it is also clear that there are other factors which are noticeably more important than cosmic ray dosage. Of course there may still be a considerable effect of altitude hidden in large fluctuations caused by other factors, which presumably are largely unknown and we cannot say that this proves anything. It does, however, give us some assurance from normal experience that the effect of eight Sunshine Units will not cause a detectable increase in bone cancer or leukemia.

This fits well with the laboratory data on animals and the limited experience on humans with radium. That is, 1 microcurie being 1,000 Sunshine Units, is still considered to be pretty safe on the basis of the laboratory data. It is set as a tolerance for occupational workers and it is therefore reasonable that eight Sunshine Units should give an effect so small as to be very, very difficult to detect. It is, I think, helpful for us, however, to realize that the present body burden of strontium-90 in new bone from the weapons tests that have occurred in the past is equal to the increase in cosmic ray intensity that goes with an increase of some 400 feet in altitude, a very small fraction of the difference in cosmic radiation intensity between Denver and sea level. Therefore, at the same time that we consider the possible effects of strontium-90 from such concentrations, we may deduce from our everyday ordinary experience limits on the effects to be expected. None of the evidence on the occurrence of bone cancer or leukemia as a function of altitude has given us any reason to believe that the present tolerance limits are in any way in error. The present body burdens in new bones are small compared to these limits.

Separate from the strontium-90 effects are the effects of general gamma radiation, the radiation that is received mainly from outside the human body, and which comes mainly from the very young fission products in the local fallout area, but which can come in smallest part from radiocesium accumulating on the ground in the case of the stratospheric fallout, or more importantly, from the shorter-lived fission products deposited by the tropospheric fallout. Of course, weapons tests are so conducted as to avoid exposures to local fallout, so our present discussion of the effects of weapons will be restricted to the much smaller gamma ray doses from the offsite tropospheric and stratospherice types of fallout. In time of war, of course, it would be the local fallout which would be of more direct concern, next to blast and thermal effects, and it is to this aspect of fallout which FCDA addresses itself in the main. In regard to nuclear tests, we have to study the effects on human genetics and the possible effects of such doses of radiation on health. Let us again apply the criterion of normal human experience to this. Measurements have shown that the general average intensity of fallout gamma rays from tests is 1 to 5 milliroentgens per year. Now

the general magnitude of the effects to be expected from this can be compared with the natural radiation intensity. We find, as mentioned earlier, that such things as living in a brick house, instead of a wooden house can amount to as much as 25 to 50 milliroentgens extra dosage per year, that there are certain areas in the world where the average dose in this country of 150 milliroentgens per year is exceeded by ten-fold, that people living on granitic rock as compared to those living on sedimentary rock receive about 70 milliroentgens per year more dosage due to the higher content of uranium and thorium in these rocks and that people living at higher altitudes have a higher natural cosmic ray dosage. Also, of course, we know that medical uses of X-rays can be considerably larger than any of these fallout dosages.

We do have experience and valid evidence that the somatic effects other than cancer and leukemia, that is, the effects of radiation on ordinary human health, require dosages which are very much larger, of the order of 25 to 50 roentgen units in order to be observed as changes in the blood and 100 to 200 roentgens for injury symptoms; whereas the dosages we are speaking of from test fallout are about one hundred thousand fold smaller.

As for genetic effects, these are extremely difficult to evaluate, since there is so little known about human genetics. But judging from experience with plants, insects, animals, and lower organisms, there is every reason to expect some genetic effects of radiation. The question is how much radiation is required for a given level of effect. There are a certain number of mutations in every new human generation. Are these largely induced by natural radiation or are they mainly of chemical, or rather biochemical origin, or both? From a chemical point of view, it seems likely that not all the spontaneous mutations in the human or any other species are caused by radiation effects, because it seems likely that radiation acts in inducing mutations mainly via molecules which it generates in the human cell, and that the mutations are caused by these chemicals and therefore in a sense are chemical in nature. Now if this be so, and the radiation induced mutations are nearly always caused by chemicals which are produced in the first instance by radiation, then chemicals themselves which are not produced by radiation but have other origins, can cause mutations, so it seems likely that a major part of the natural or spontaneous mutations in any species is not radiation induced. This point is an important one to settle, for the reason that we have to compare the effects of fallout radiation with the fraction of the natural spontaneous mutations which is due to the radiation we are normally subjected to. In other words, if the normal mutations are all due to radiation, then the effects of the additional radiation from general test fallout, or from other sources of radiation such as atomic power, or the medical uses of isotopes and X-ray, will be larger. It seems likely, and many genetic authorities agree on genetic grounds with this conclusion, that a major portion of the spontaneous mutations of the human species is not due to radiation but due to other causes. Therefore, a fraction of the spontaneous mutations in the human species is taken as being due to irradiation. Now, what this fraction is, it is difficult to say, but Professor H. J. Muller has estimated that this might be 10 percent. Therefore, one estimates the 150 milliroentgens per year from natural radiation now causes about 10 percent of the spontaneous mutations, and therefore, that the test fallout if continued indefinitely will, at the present level of about 1 to 5 milliroentgens per year, cause an increase in the natural spontaneous mutation rate of something like $\frac{1}{50}$ of ten percent, or 0.2 of a percent of the spontaneous mutations. In the extreme, if it should prove that all of the spontaneous mutation rate is radiation induced despite the chemical arguments, the effect would be ten times as great, or two percent. Dr. Dunning of the Division of Biology and Medicine of the AEC estimated 1.4 percent in 1955 on similar assumptions. (The Scientific Monthly *81*, 265–December 1955.) This effect is one which is comparable to moving to a slightly different locality and is much less serious than changing from one house to another or doing any of a dozen things. The only important point is that genetic effects show only if large numbers of people are subjected to them. Therefore, we would expect that the effects of large populations changing their environment, such as living at a higher altitude, or living in a region of naturally higher radioactivity, should cause genetic effects, if test fallout does so. An examination of vital records should be made to test for such effects and the Atomic Energy Commission is doing so as best it can. The United Nations Scientific Committee on the Effects of Atomic Radiation has been comparing the data on natural background dosages, and it is hoped that this study will be continued and that the search will be made for observable effects of variations in the natural background dosage, for it is certain that any effects

due to gamma rays from fallout must be already present in much larger measure due to the natural dosage.

II. VARIATION IN INDIVIDUAL STRONTIUM-90 BURDENS

What is the likelihood that even though the average strontium-90 content be well within tolerance limits, that a few individuals should exceed tolerance limits, that a few individuals should exceed tolerance limits? Let us consider first the case which will ultimately hold, the situation of complete equilibrium with the environment in so far as the strontium-90 burden is concerned. The only way we can make judgments about the expected individual variations from the mean concentration is by direct experiment on human body composition, not only for strontium-90 but for other analogous constituents. Most of the recent data on the strontium-90 body burden are from odd bits of bone removed during surgical operations, but fortunately we have actual data for the strontium-90 content of the entire bodies of some several dozen stillborn children [1] in the city of Chicago in the year 1953. A strenuous effort is now being made on the Sunshine Project to continue this series and also to check the human bone data by analyses of complete skeletons. We present the distribution of the strontium-90 data for the stillborn children in Figure 1. Data for the occurrence of ordinary non-radioactive strontium in human bones also have been published.[2] These obviously refer to the full steady state condition and are obviously at least as nearly in equilibrium with the environment as the fallout radioactive strontium ever will be. These data are presented in Figure 2. The occurrence of radium in the human body also has been used since it is chemically similar to both calcium and strontium, and therefore is a bone seeker and because it is obviously also in steady state equilibrium. The data used were those by Palmer and Queen [3] in Figure 3. And, finally, we use the recent data on occurrence of normal potassium in human bodies as determined by Anderson and Langham [4] at the Los Alamos Scientific Laboratory as presented in Figure 4. All of these data show a normal frequency distribution as indicated by the theoretical curves. The respective widths of the curves (standard deviations) are 36 percent for radiostrontium, 40 percent for normal strontium, 40 percent for radium, and 18 percent for natural radiopotassium. It is completely clear from these data that they agree with one another in general shape and that the magnitude of the distribution of the strontium-90 contents of the Chicago stillborn babies was not in any way anomalous. Therefore, we shall take the distribution curve for radiostrontium to be the same as for the normal strontium data. The occurrence of non-radioactive normal ordinary strontium in the bones should certainly tell us what the equilibrium distribution will be for radioactive strontium, and from it we should be able to learn the points about distribution which we cannot yet learn in any detail from the radioactive strontium itself. Turekian and Kulp noted in their study of normal strontium in human bone that in a given region the deviation from the average was about 34 percent of the average, that is, for human bone from the regions Colorado, Texas, Cologne, Bonn, Venezuela, Chile, Vancouver, China, and India. In each instance the ratio of the standard deviation from the mean itself was taken and the average calculated to obtain 34 percent. Therefore, we take 34 percent as the expected standard deviation from the mean *for a given locality* for the eventual strontium-90 equilibrium burden in human bones.

With this result we can, assuming a normal error curve shape of the distribution of probabilities, answer the immediate question: What is the probability of an individual exceeding the tolerance even though the mean does not? On the basis of this analysis we find that at steady state and in equilibrium the variation from the mean will constitute an error curve with a shape corresponding to the standard deviation, being ⅓ of the mean. Therefore, at steady state among people living in a given locality, only one person in about 700 will have more than twice the average strontium-90 burden, and the chances of anyone having as much as three times the normal burden will be about one in twenty million.

Now what about the non-equilibrium distribution, when the strontium-90 is finding its way into the biological system? Obviously, the burden will be much

---

lower here, but the deviation from the mean will probably be much higher percentagewise, particularly in adults where most of the bone has been deposited before strontium-90 was produced. The present strontium-90 content of adults depends very much on the growth rate and the metabolic activity of the various bones in the given individual's body which happens to be sampled. However, the specific concentration of the strontium-90 deposited will not exceed that in new bone developed entirely in the present biological environment, i. e., the local concentration in adult bone will not exceed that for the whole bone in young children, whose total bodies are composed of the mixture of strontium-90 and calcium which now is present in food. Since the present ratio for children to adults is about four to one for average total strontium-90 content, the factor of concentration in adults' active bone regions may be as much as four-fold greater than the whole body average. Thus the apparent spread for random bone samples taken from adults should be very large compared to the true equilibrium spread for these reasons. As equilibrium is approached, however, the spread must decrease very, very markedly.

The data on human bones indicate a very wide scatter, but it seems extremely clear that the variation is a reflection of the fact that the main skeleton of adult individuals is not in equilibrium with the present food supply, and that the variations reflect the different rates at which the various bones in the bodies of individuals are coming into equilibrium with the food supply in the general biological environment. A study of whole skeletons taken from one given locality which is now under way as a part of Project Sunshine will clarify the point about the variations among individuals in their rate of coming into equilibrium with the general biological environment. This study is under way in Dr. Kulp's laboratory.

It should appear from these studies that the variation from the mean of adults will be larger than the factor of one-third which apparently is normal for the types of equilibrium distribution considered above. It is, of course, very important to establish the truth of this prediction clearly. However, the general agreement in shape of the distribution curves for such widely different materials as normal potassium in whole bodies, radium, and normal elementary strontium in fragmentary human bone, and actual fallout radioactive strontium in the whole bodies of stillborn children, give us good reason to believe that there is nothing extraordinary in the distribution of radiostrontium in human bone.

III. VARIATION OF THE STRONTIUM-90 BODY BURDEN WITH LOCALITY

Most important of the causes of variation of the strontium-90 content of individuals with locality is, of course, the amount of fallout in a given region. The general rules about the intensity of fallout have been described above. For air-fired megaton weapons our present indication is that the fallout is almost world-wide and for reasons of simplicity and in the absence of better information at the present time, we work on the model that this is a uniform distribution, over the entire world, of material that falls from the stratosphere. Further evidence and data on this point are rapidly being collected which will undoubtedly settle the stratospheric horizontal mixing question.

At the present itme, the general latitudes in the Northern Hemisphere which are betwen 10° and 60° North have the highest strontium-90 content. In the United States, which because of our proximity to the Nevada Test Site has unusually high fallout, there are at the present time about 25 millicuries per square mile of strontium-90. For average soil this means a concentration in the top soil of about 50 Sunshine Units. With the factors of discrimination mentioned above, this means that an equilibrium body burden between 1.7 Sunshine Units and 3.9 Sunshine Units is to be expected. Actually, the present body burden in young children indicates that the lower value is probably more realistic. The present body burden in children—about 0.5 Sunshine Units—probably was derived from an average strontium-90 content in the top soil of something like 15 millicuries per square mile, or about 25 to 30 Sunshine Units during the time the strontium-90 was being acquired. Thus we find that the experimental value for the ratio between the body burden of young children and the average concentration in the top soil is about 50 to 1; rather closer to the higher range of the laboratory results than to the lowest range.

Table II contains the latest data for the total strontium-90 fallout as measured in U. S. soils, and Figure 5 displays these data graphically.

The Northern part of the United States has about 20 to 30 millicuries of strontium-90 per square mile, the Southern States are somewhat lower. The low figure of 7 millicuries per square mile for Grand Junction, Colorado, is probably due to local climatic and sample site conditions.

TABLE II.—*Health and safety laboratory 1956 survey of United States soils for Strontium-90—Samples taken between Oct. 8 and 13, 1956—Strontium extracted with 6N HC1 at room temperature—Replicates represent individual soil aliquots taken after sampling and air drying—Each error term represents 1 standard deviation due to counting error*

The differential rates at which the fallout has been occurring probably are best measured by the so-called "pot collection" method. A bucket with vertical walls of appreciable height is placed out in the open and allowed to collect the total fallout for a given period including the rain, snow, dust, etc. The bucket is left out whether it has rained or not and covers the total fallout for a given period. Figures 6 and 7 give the curves so obtained for New York and Pittsburgh areas together with the estimated errors of measurement. It is interesting to note the changes in slope and to correlate them with the occurrence of test activitis and the relatively short-lived troposheric fallout. The minimum slopes which appear during quiet periods when no one is testing are the stratospheric fallout of which we have spoken and these slopes when we have enough pots operating all over the world will, when taken together with the results of the measurements of the amounts of radiostrontium and radiocesium in the stratosphere, give an accurate value for the stratospheric residence time and settle the mixing question.

In addition to the intensity of fallout, the question of the fraction of the radiostrontium, and, for tropospheric fallout, the radioiodine of eight-day half-life, that is in assimilable form is an important one. So far most fallout strontium appears to be completely water soluble and therefore most assimilable, though continued tests on this point should be made. Direct leaf pick-up of course promotes assimilation of the strontium because the plant differentiation against strontium when it assimilates it from soil thus is avoided. Another factor is, of course, the concentration of available calcium in the soil. By available calcium we mean calcium which is available to plants and not the total calcium in the soil. It is known that soils which are high in available calcium produce plants of lower radioactive strontium content; that is, the radioactive strontium to calcium ratio in the plant is lower as a direct consequence of the lower concentration of radiostrontium in the available soil calcium. In addition, as mentioned previously, plants tend to prefer calcium to strontium with a discrimination factor of about 1.4. Sheep which grow in certain areas of Wales have shown concentrations in their bones approaching 150 Sunshine Units, while sheep and cattle growing in the U. S. have hardly ever exceeded one-fifth of this. The Welsh soil in certain areas is very low in calcium and as a result grows grasses of high radiostrontium content. Of course, it is clear that fertilization with calcium will immediately relieve this difficulty, but in the absence of such fertilization, the question is: How serious is the effect of calcium deficiency in promoting strontium-90 pick-up through the food chain?

As was remarked earlier, there is an averaging which occurs in food distribution systems and calcium deficient soils are naturally rather poor producers and as a consequence the weight of the food so produced is less than for a good well fertilized, well balanced soil. This factor reduces the flow into the general food system of material of exceptionally high strontium-90 content. It therefore will probably be sufficient to consider the radiostrontium of milk, since milk is the main source of calcium, in order to test for the radiostrontium content of the food in given areas. Direct measurements have shown that a factor of five encompasses the total variation due to all factors including calcium deficiencies in acid soils.

The general intake must depend on the food distribution pattern and the relatively small fluctuation in milk contents must reflect this. The number of individuals who rely totally on the food output of soil of very low calcium content is very small indeed, but it must be true that these individuals if they grew up on such a provincial, isolated farm would have as much as ten to 50 times the normal average strontium-90 content. The normal calcium concentration in soils in the United States is about 20 grams per square foot for the top 2.5 inches and about the poorest soil known has about 0.4 gram available calcium per square foot for the top 2.5 inches—a deficiency factor of 50.

It is clear from a detailed examination made by the author for people living in calcium deficient areas with normal food distribution patterns, that a factor of 5 is about as large an effect as can be expected from a fifty-fold deficiency of calcium in the soil. The food from outside of the calcium deficient area reduces by a factor of about ten the increase in strontium-90 pick-up rate which would be expected from the calcium deficiency in the soil if people lived entirely off the soil for their whole growing period of 20 years or so.

The food of lowest strontium-90 content is fish flesh, because of the great dilution the fallout receives by the hundred meters of sea water above the thermocline which rapidly mix with the fallout within a few hours or days. This means that

the specific concentration of radioactive strontium, or any other fallout constituent in sea water, is relatively very much lower than it would be in soil. For example, 100 meters of sea water has 370 grams of dissolved calcium per square foot as compared to the average of 20 grams per square foot for the top 2.5 inches of soil which absorbs and holds the fallout radiostrontium. Therefore, in principle sea food and fish are lowest among foods in content of radiostrontium fallout.

IV. EFFECTS OF CONTINUED TESTING AND GENERAL CONCLUSIONS

In summary, then, we see that the present body burden of strontium 90 from atomic weapons tests in the United States corresponds to the radiation dosage to the bones which would result from a few hundred feet increase in altitude, and the present vital statistics show no observable effect on the occurrence of bone cancer or leukemia of much larger changes in altitude. The tolerance figure of 100 Sunshine Units, or 0.1 of a microcurie for an average individual, or 100 micromicrocuries per gram of body calcium, that is recommended now is about two hundred times the present level for new bone in the U. S., and it will be exceeded by fallout from weapons tests in any foreseeable circumstances.

The distribution of strontium–90 burdens among individuals *for a given locality* will be a normal error curve with a standard deviation of about one-third of the average concentration. This means that about one individual in 300 will have more than twice the normal average value for a given locality, and that about 1 in several million will have three times the average value.

The effect of locality is more important, however, particularly in the effect of calcium deficiency in the soils. Careful consideration of this question indicates that there will be very few individuals who show a strontium–90 content which is strictly inversely proportional to the available calcium concentration of the soil in their region. This is due to the fact that food distribution systems automatically average over a wide area and people assimilate their calcium slowly. Most people drink milk and eat cheese and other calcium-bearing foods from a rather wide area, and this effect reduces by an estimated factor of ten the potential effect of calcium deficiency in the local soils.

On the basis of laboratory experiments the human body concentration of strontium–90 at equilibrium will be between 13 and 30 times less than that in the top soil. The present data indicate that the higher figure is closer to the truth, and so we will be conservative in taking the figure of 20 for this ratio. Therefore, the present burden of 50 Sunshine Units in the top soil of the United States may eventually lead to as much as 2.5 Sunshine Units in the human bones, but more likely will lead to about 1.7.

Of course, as testing continues and more fallout occurs, the levels will rise. The strontium-90 that still resides in the stratosphere at the present will fall out according to our expectations at a rate which just about compensates for the decay of the material already deposited, so that no great additional increase from this source is to be expected from weapons fired in the past. If the testing should continue at about the same rate as it has averaged over the last five years, then we should at equilibrium, after an infinite time, approach a level of 8 times the present rate, since the average life of strontium-90 is 40 years. This assumes that the future testing will be conducted so as to give in each future five-year period the same as the last five have. And so we would expect in the United States at that time an average human strontium-90 concentration of 20 Sunshine Units with the conservative factor of 20 between the top soil concentration and the concentration in human bone, or 5 Sunshine Units if the factor of 80 is used. In other words, in the United States something between 5 and 20 Sunshine Units would be the equilibrium concentration of human bones if testing continued indefinitely at the average rate of the past five years. This level would be approached only after a few decades. After 28 years the level would be half of this equilibrium value, and after another 28 years, 56 years total, from an arbitrary beginning which we have set as 1952, we would expect in the year 2008 three-fourths of the equilibrium figures. So somewhere between 4 and 15 Sunshine Units of strontium-90 in human bones in the United States might result from the present type of testing being continued for the next 50 years.

In those certain areas in the world where the soil is low in calcium, this level might go five-fold higher. At the present rate of testing we might indeed approach the figure of 100 Sunshine Units, the tolerance limit for large populations, at the beginning of the 21st century for these certain limited regions in

the world. The observed conditions in these regions could be relieved, however, by fertilization of the soil with calcium, either calcium nitrate or lime being used, as appropriate from other considerations.

The Sunshine Project continues to study the problems of world-wide fallout—the stratospheric inventory of radiostrontium and radiocesium, the occurrence of these isotopes in the soils and water and the biosphere all over the earth, the biological effects at certain levels of contamination with strontium-90, and to a lesser degree with cesium-137, and the possible genetic effects of the low gamma ray dosages associated with world-wide fallout from atomic tests. All of these are studied not only with the point in mind of devising methods of protection against atomic warfare, but also with the thought of possible application in the remote event of industrial accidents which may happen in connection with certain of the peaceful uses of atomic energy, particularly atomic power. Certainly an understanding of the basic principles of world-wide fallout is applicable to the control and safe-handling of isotopes. All of this is done in collaboration with the United Nations Scientific Committee on the Effects of Atomic Radiation, and it is to be hoped that as the data appear all of the countries in the world will join together in this international effort to understand better the effects of the great new fact in life, the nuclear atom.

APPENDIX 2

BRITISH STATEMENTS, REPORTS, AND ARTICLES ON FALLOUT AND RADIATION EFFECTS

MEDICAL RESEARCH COUNCIL

THE HAZARDS TO MAN OF NUCLEAR AND ALLIED RADIATIONS

Presented by the Lord President of the Council to Parliament by Command of Her Majesty
June 1956

93299 O—57—pt. 2——35

To The Most Honourable
THE MARQUESS OF SALISBURY, K.G., LORD PRESIDENT OF THE COUNCIL

My Lord,

On the 29th March, 1955, the Prime Minister, through you, requested the Medical Research Council to appoint an independent committee to report on the medical aspects of nuclear radiation, including the genetic aspects. The Council accordingly appointed a committee, under the chairmanship of Sir Harold Himsworth, and this body has now reported.

The report has been accepted by the Medical Research Council, and I have been authorised to transmit it to you with a view to its presentation to Parliament. It is the wish of the Council that, in so doing, I should express their high appreciation of the care, thought and ability which all members of the Committee have devoted so freely to their most difficult and important task.

I have the honour to be, my Lord,
Your Lordship's obedient Servant,

LIMERICK,
Chairman,
Medical Research Council.

June, 1956.

THE HAZARDS TO MAN OF NUCLEAR AND ALLIED RADIATIONS

A REPORT TO THE MEDICAL RESEARCH COUNCIL

CHAPTER I

INTRODUCTION

1. In accordance with the undertaking of the Prime Minister given in the House of Commons on the 29th March, 1955, the Medical Research Council, in April of that year, appointed us members of a committee, under the chairmanship of Sir Harold Himsworth, to review the existing scientific evidence on the medical aspects of nuclear and allied radiations, and we have unanimously signed this report.

2. We held our first meeting on the 3rd May, 1955, and decided to carry out our enquiry for the most part through two panels, one of which undertook to consider the effects of radiation on the health of the individual, and the other the possible genetic consequences of radiation to the population as a whole as well as to the individual and his descendants. Sir Ernest Rock Carling, Professor A. Haddow, Professor A. Bradford Hill, Dr. J. F. Loutit, Professor W. V. Mayneord, Dr. F. G. Spear, Professor Sir Lionel Whitby and Professor B. W. Windeyer have served on the former panel, which has met nine times. Professor A. Bradford Hill, Professor K. Mather, Professor P. B. Medawar, Professor J. S. Mitchell, Professor L. S. Penrose, Sir Edward Salisbury and Professor C. H. Waddington have served on the latter, which has met eleven times. In addition, Sir John Cockcroft and Professor J. R. Squire have served on the main committee. Both panels have worked under the chairmanship of Sir Harold Himsworth and all papers have been circulated to every member of the committee. More than seventy specially prepared papers have been considered, some of them written by scientists not serving on the committee, and we have drawn widely on the relevant published material. Groups to consider special problems have been appointed as the need arose. We have also taken into account relevant work carried out under the auspices of the Medical Research Council's Committee on Protection against Ionizing Radiations, and the recommendations and discussions of the International Commission on Radiological Protection. On the completion of the work of the panels, we have met together in full committee to consider our conclusions and to draw up this report. We have held four meetings of the whole committee during the period of our enquiry.

3. Throughout the course of our work, and in the preparation of this report, we have been greatly helped by our two scientific secretaries, Dr. W. M. Court Brown and Dr. T. C. Carter, of the scientific staff of the Medical Research Council. We are also very much indebted to Dr. R. H. L. Cohen and to Dr. Joan Faulkner, of the Council's headquarters staff, who have been responsible for co-ordinating the work of the panels and the various special enquiries that we have initiated.

4. The immediate occasion for the Government's request to the Medical Research Council to set up this Committee was the widespread public concern

about the long-term effects of nuclear weapon testing. This is only one aspect, however, of the much larger problem arising from the increasing use of ionizing radiations. It is already apparent that the future development of our civilisation is closely bound up with the exploitation of nuclear energy. At present, the potential hazards from its possible military uses overshadow in many people's minds the vast potentialities for good of this new source of power. The hazards to health are qualitatively the same, however, whether they arise from nuclear weapons or from the use of ionizing radiation for peaceful purposes. The difference is one of degree and intensity only. As with other sources of energy that man has harnessed to his service, the use of ionizing radiation necessarily entails risk; but the risk is controllable within limits that he can accept. It is the purpose of this report to indicate the nature of the risks and the extent to which they can be controlled.

5. Our purpose has been to give as firm a guide as the evidence allows to informed opinion in the country as a whole, and more especially to those with whom lies the responsibility for practical decisions of policy. This has laid on us the duty of drawing more precise conclusions than we might wish to do on purely scientific grounds, and we feel bound to point out that in the course of our enquiry we have become increasingly aware of the impossibility, in the present state of knowledge, of coming to final conclusions on many questions of importance in the subject under study. Nevertheless, because of the many and urgent problems on which action cannot be delayed, we have felt it incumbent upon us to attempt to give guidance to the best of our ability. It is inevitable that, with the advance of knowledge, many of the views which we have expressed will come to require amendment, but we feel reasonably confident that the general picture which we have drawn is unlikely to be found grossly inaccurate in perspective or scope.

6. We wish to remind those who read this report that human populations have always been exposed to ionizing radiation, and that it is the scale and not the nature of the hazard which is new. Moreover, our remarks in many respects can be applied only to large populations living under conditions similar to those prevailing in this country. A technically advanced community, such as our own, is likely to be exposed to a greater risk from the industrial and medical uses of atomic energy. These risks have to be weighed against the established benefits derived from the use of ionizing radiation in industry and medicine, and against the benefits likely to be conferred in the future.

7. We have thought it helpful to the general reader to follow this introduction with a brief account of radiation and its mode of action on living cells (*Chapter II*). The types of radiation and the units in which they are measured are described, and the chapter concludes with an outline of the way in which radiation acts on living tissues.

8. In *Chapter III* consideration is given to the effects of radiation on the health of the exposed individual. A brief review of the available sources of information is followed by an account, first, of the clinical manifestations which may occur within a short time of exposure, and, secondly, of the effects which may appear a considerable time, perhaps many years, afterwards. The chapter includes a discussion of the evidence from a detailed study of the relationship between radiation dose and the incidence of leukaemia in patients suffering from a particular disease. This study was undertaken at our request by members of the Medical Research Council's staff, and we should like to thank Dr. W. M. Court Brown and Dr. R. Doll, who carried out the work, for the great help that they have given us. The full results of the enquiry are to be published separately and are summarised in Appendix B.

9. *Chapter IV* of the report opens with a short account of the biological processes controlling the hereditary constitution in human beings, and proceeds to a description of the way in which radiation might affect the genetic structure of human populations. An attempt is then made, in terms of the incidence of certain specific grossly harmful conditions, to assess the consequences for the individual and society of increasing the rate of mutation, and to define the levels of dose which might be expected to bring about such an increase.

10. In *Chapter V* the contributions made to the present level of radiation by naturally occurring radioactivity and by the medical, industrial and other uses of ionizing radiation are reviewed. Many new data have been obtained, and an investigation has been initiated at our request, and is still in progress, to establish more precisely the contribution from various diagnostic and therapeutic procedures (Appendix K). An assessment is then made of the results of contamination from the fall-out from atomic and thermonuclear test-explosions, and the chapter concludes with a brief description of the nature of nuclear warfare.

11. *Chapter VI* sets out our assessment of the hazards of ionizing radiation on the basis of the evidence put forward in the earlier chapters and proceeds to a discussion of the dangers from radiation in peace and war.

12. *Chapter VII* contains a summary of our report which is followed by a statement of our conclusions.

13. The highly technical nature of this report has made it necessary to devote some space in each chapter to a description of generally accepted scientific theory in terms comprehensible to the general reader. No attempt has been made to prepare a bibliography for these parts of the report. Where new material has been drawn upon or controversial topics are discussed, the evidence has been set out in greater detail in appendices, to which lists of selected references to published work have been attached.

14. It will be evident to any reader of this report that, at the present time, there are many large and serious gaps in our knowledge of the medical and biological effects of ionizing radiation. If the potentialities for good are to be exploited with confidence and safety, it is necessary that these gaps should be filled. Much research on many broad fronts will be required. Given the necessary facilities, there is no reason to doubt that the information can be obtained; and we attach the greatest importance to the recommendations for future work that we have been invited to submit for the consideration of the Medical Research Council.

CHAPTER II

THE NATURE OF RADIATION AND ITS ACTION ON LIVING CELLS

Introduction

Discovery of X-rays

15. The transference of energy from sun to earth by radiant heat and light was already well recognised when in 1895 the discovery of X-rays revealed something quite novel—namely rays which had the power of penetrating normally opaque objects. The power of penetration varied in relation to different tissues of the body, and this variation enabled shadow pictures of internal structures to be seen, and so laid the foundation of the first great use of the new discovery. Almost by accident it came to be recognised in the next few years that part of the radiation was absorbed in the tissues, with the production of physico-chemical changes which could lead to biological damage.

Discovery of natural radioactivity

16. The production of X-rays was soon followed by the discovery of natural radioactivity. It was found that compounds of certain heavy elements in the earth's crust, such as uranium and radium, spontaneously emitted rays which had similar properties to X-radiation, although they were of different penetrating power. Later, rays were identified which reached the earth from outer space and these were named 'cosmic rays' *.

Disintegration of radioactive elements

17. The radiation emitted from radioactive elements is due to spontaneous disintegration of their atoms, with the production of one or more types of radiation and of a new element lighter in weight than the original one. A radioactive element, such as radium, may be regarded as a population of atoms, each of which has a length of life ending in spontaneous break-up of the atomic nucleus with emission of radiation, partly in the form of a stream of particles and partly as wave-propagated radiant energy. In this way the amount of radium gradually diminishes. While the moment of disintegration of any particular atom is unpredictable, the rate of decay of the population of atoms as a whole follows a strictly constant rule. Thus, any group of radium atoms decays to half its original number in a period of about 1,600 years. This period, called the half-life, varies widely for different radioactive substances but for each it is constant and characteristic. Sometimes the new element formed by atomic disintegration is itself unstable and a cascade of successive disintegrations occurs, each with the emission of one or more types of radiation, until finally a stable non-radioactive substance is formed.

Radioactive isotopes

18. After much pioneer work, dating from Rutherford's experiments as early as 1919, it was found possible in the nineteen-thirties to turn many normally stable elements into unstable versions of their original form, by treating their nuclei with suitably energetic radiations, and so to produce artificial radioactive substances. At first it was only possible to make these

* For a description of cosmic rays see paragraphs 192–193.

artificial radioactive substances under very special conditions and on a very small scale. The expansion of nuclear research during the last war, however, led to the development of the nuclear reactor, by means of which it became possible to create radioactive substances in very large quantities either directly or as by-products of the fission* processes in the reactor itself. Both natural and artificial radioactive substances are now commonly called radio-isotopes.

Types of Radiation and Units of Measurement

19. Several different kinds of penetrating radiation are known, of which the common types are the following:

alpha particles: These are the nuclei of helium atoms and are swiftly moving particles of high energy, carrying a positive electric charge. They have little power of penetration, passing into soft tissues for only small fractions of a millimetre, and irradiation of the body from outside with alpha particles is consequently of little significance. They may, however, affect living tissues when they arise from radioactive materials actually within the body, and, in sufficient quantity, they are then biologically very destructive.

beta particles: These are fast-moving energy-carrying particles (electrons) of very small mass with a negative charge. The amount of energy that they carry may vary considerably and their power of penetration will vary accordingly. In general, beta particles are more penetrating than alpha particles and can traverse distances of up to about a centimetre in soft tissues. For this reason they are valuable therapeutically, and radioactive substances emitting beta radiations are used for the destruction of superficial tumours. For the same reason heavy doses from outside the body can damage the superficial tissues and, if beta-emitting substances are ingested, destructive effects within the body may be produced.

gamma rays: These are electro-magnetic radiations of high energy emitted by atomic nuclei. Like alpha and beta particles they are produced in the process of natural or artificially induced atomic disintegration. Gamma rays have great penetrating powers in comparison with alpha and beta particles and the more energetic gamma rays can traverse the whole body with relatively little absorption. As a result, almost the whole thickness of the body may be irradiated by gamma radiations and this is a deciding factor in producing the general illnesses which may follow this type of irradiation. The properties of gamma rays are essentially similar to those of X-radiations but in general gamma-rays have an energy and penetrating power corresponding to the more penetrating X-rays produced at such extremely high voltages as several million volts.

X-rays: These are similar wave-propagated radiations, which are usually produced artificially by electrical machines and which are widely used both diagnostically and therapeutically in medical radiology. They vary considerably in their penetrating power, according to the electrical energy used in their production. The biological effects of X-rays are brought about by high-energy electrons, which are liberated in the tissues during the passage of the rays, so that the biological action of X-rays and beta particles is essentially the same.

neutrons: These are normal constituents of atomic nuclei but may be liberated with considerable energy. They carry no electric charge and

***Fission:* The splitting of the nucleus of a heavy atom into two roughly equal parts with the release of a large amount of energy.

are therefore not repelled by the charged nuclei of atoms, but enter into them to build up unstable structures which often disintegrate with the production of artificial radioactivity. Fast neutrons act chiefly by collision with the hydrogen of the water and of the other compounds which the tissues contain, the resulting 'recoil hydrogen nuclei' somewhat resembling alpha particles in their action. The initially fast neutrons are gradually slowed down in the tissues and may then bring about biological effects by interaction particularly with nitrogen. They may also be captured by hydrogen, thereby releasing energetic gamma rays.

Ionization

20. These several types of radiation vary not only in their powers of penetration but also in relation to the number of electrically charged atoms and molecules, called ions, that they leave in their tracks as they pass through tissues. For this reason they are collectively known as ionizing radiations. It is the production of electrically charged particles, or ions, which is mainly responsible for initiating the physico-chemical changes in living tissue that lead ultimately to the production of overt radiation damage. The efficiency of a given dose of radiations in producing biological effects can be related to the numbers of ions produced per unit length of track.

Intensity of dose and length of exposure

21. The biological effects of radiation are closely related to the dose, or quantity, of radiation received. An analogy can be drawn with the effects of ultra-violet light on the skin in producing sunburn. It is well known that these effects depend on two main factors, the brightness of the sunshine and the length of the exposure to it. Similarly, the effects of radiations such as gamma rays, X-rays or beta rays are determined by the same two factors, the intensity of the radiation and the period of exposure. Radiation may be regarded as consisting of small units of energy called 'quanta', and the intensity of the beam of a given kind of X- or gamma rays is simply a measure of how many such quanta are striking a particular area in a given time. The dose of radiation might therefore be described as the energy which is absorbed in the small mass of tissue upon which the radiation impinges. Living tissues, however, are not inert. After some types of damage by radiation, repair processes take place and the rate at which the dose of radiation is given becomes an important factor in determining the observed biological effect. Thus, if a dose of radiation is spread out over a very long time, for example many years, the response may be very much smaller than or even quite different from that which would occur if the same amount of radiation were given in a very short time. On the other hand, with some well known forms of biological damage produced by ionizing radiations, recovery does not occur. The production of gene mutation is perhaps the most important example of this latter type of change.

Measurement of dose: the roentgen

22. The difficulty of making satisfactory measurements of the dose of radiation has been overcome by making use of the changes of electrical conductivity which are brought about in air when ionizing radiations pass through it. This particular method of measurement is used, not only because it is technically convenient but also because the atomic composition of air or water is in this respect essentially similar to that of the body, the

absorption of X-rays taking account only of the kind of atoms present and not of their particular chemical combinations. The unit of dose which has hitherto been adopted internationally is called the roentgen,* which is abbreviated to the letter 'r'; for very small quantities of radiation the milliroentgen (0·001 r) is often used as the unit. The intensity of radiation to which we are ordinarily exposed from our natural surroundings is about 0·1 r per year.

Measurement of radioactivity: the curie

23. It has been seen that the biological effects of radiation depend upon the amount of energy which is absorbed in the tissues. At each radioactive disintegration, an atom emits a certain amount of energy in the form of high-speed particles and gamma rays. The total rate at which the tissues are irradiated therefore depends on how many atoms disintegrate per second. In considering the effects of radioactive materials actually within the tissues, use is accordingly made of units of radioactivity which depend on the number of atomic disintegrations per second. Based originally upon the rate of disintegration of radium, the unit of radioactivity is called the curie and represents the amount of an element in which $3{\cdot}7 \times 10^{10}$ disintegrations occur per second. This is too large an amount of radioactivity for most biological work and it is customary to measure the amounts of radioactivity in the body in microcuries (millionths of a curie). For some radioactive materials the maximum amounts which can be allowed in the body are of the order of only one microcurie or less; but even this very small amount of material corresponds to many thousands of atomic disintegrations per second.

Relative biological efficiency

24. The destructiveness of the different types of radiation can also be expressed in relation to that of an equivalent amount, in terms of energy, of gamma rays. This measure is known as the relative biological efficiency (R.B.E.) and varies between different tissues.

Action on Living Tissues

25. The basis of the biological action of ionizing radiation is not fully understood. The consensus of opinion is that radiation acts primarily upon the cell and its constituents, and upon the complex chemical processes occurring in these, rather than upon the fluids in which the cell is bathed. It is thought that the processes associated with the formation of ions during the passage of radiation lead to changes in some of the highly organised molecular systems within the cell. These changes are probably brought about by highly reactive chemical intermediates liberated within the cell subsequent to the physical process of ionization.

Effect of radiation on organisms, tissues and cells

26. All living tissue is killed if exposed to large enough doses of radiation. Different types of organisms, tissues and cells, however, vary greatly in the amount of radiation which they can withstand. Among mammals the dose of X-rays to the whole body which will kill 50 per cent of an animal population varies from 200 to 1000 r—depending on the species; for man it is thought to be between 400 and 500 r. There is also a wide variation in sensitivity between different animal tissues. For instance, in man the most sensitive tissues include the lymphatic glands, the epithelium of the small

* The roentgen shall be the quantity of X- or gamma radiation such that the associated corpuscular emission per 0.001293 gramme of air produces, in air, ions carrying 1 electrostatic unit of quantity of electricity of either sign.

bowel, and the precursors of the blood cells which are situated in the bone marrow, whereas adult nerve and muscle tissue are comparatively insensitive. Variations in sensitivity also occur at different stages in the life cycle of a cell; for example, cells about to divide are often more sensitive than those in the resting state.

Repair processes

27. At dose levels below those which damage tissue irretrievably, the situation is modified by processes of repair; but a distinction must be drawn between true recovery, in which the damaged cells return to normal form and function, and the replacement of injured cells by those coming from outside the field of radiation. The latter is the more conspicuous form of repair after heavy radiation damage in the higher animals and leads to the original tissue being replaced by simpler unspecialised material or scar tissue. Repair processes within the individual cell are little understood and still largely a matter of speculation, but they must play an important part after low doses.

CHAPTER III

THE EFFECTS OF RADIATION ON THE HEALTH OF THE INDIVIDUAL

Introduction

28. Experience of the effects of ionizing radiations has been accumulating with increasing rapidity since the benefits which they may produce in the treatment of malignant disease first began to be appreciated. This experience has been limited, in the main, to the effects produced by the relatively large doses which it is often necessary to give to the area of the body under treatment. More recently, knowledge of the effects of very large doses to the whole body has been obtained as a result of the atomic bomb explosions in Japan. In this chapter it will be necessary to draw heavily on the information from these two sources in considering both the acute and the long-term effects of exposure to radiation, but the reader must bear in mind that such information is only indirectly relevant to the circumstances of ordinary civilian life, since doses of this magnitude would only be conceivable in the immediate vicinity of an accident in a nuclear reactor.

29. There is much less information about the possible effects of chronic exposure to very low doses of radiation, such as those to which special groups of workers may be exposed in the course of their occupations. At a time like the present, when nuclear energy is being intensively developed for civil use, the importance of obtaining such information cannot be exaggerated. The investigation which we have sponsored on leukaemia was undertaken in an attempt to obtain information on the relationship between the size of the dose of radiation and the incidence of the disease among patients with ankylosing spondylitis, so that conclusions might be drawn about the effects of lower doses. The investigation must be regarded, however, as only the first step towards this goal.

Sources of Information

30. Information about the effects of radiation on man has been derived from four main sources: radiotherapeutic experience; occupational experience, including that from accidents; experience from atomic bomb explosions; and animal studies.

31. *Radiotherapeutic experience.* Both X-rays and the gamma rays of radium have been used for many years in the treatment of disease, mainly in the treatment of cancer. Observation of patients receiving radiotherapy has yielded information on the general effects of radiation and on the effects produced in different tissues; and the therapeutic use of radioactive isotopes has provided data on the effects of radioactivity within the body.

32. *Occupational experience.* Information on the occupational hazards of radiation has been obtained from studies of three groups of workers: medical radiological workers, painters of luminous dials for watches and clocks, and miners working radioactive ores in the Schneeberg mines in Saxony and in Joachimsthal. The experience of these three groups serves to illustrate three different forms of radiation hazard. The radiological workers were exposed mainly to external irradiation by X- and gamma rays, and some developed

skin damage leading to skin cancer, or bone-marrow damage leading to severe diseases of the blood. The luminous-dial painters ingested paint containing the naturally-occurring radioactive elements radium, mesothorium and radiothorium, which are retained within the skeleton, and some developed bone tumours. The miners of Joachimsthal and Schneeberg worked in an atmosphere containing high concentrations of the radioactive gas, radon, and many developed lung cancer. The study of these three different hazards has contributed greatly to our knowledge of the harmful effects of radiation, and has provided data for the formulation of safety standards.

33. *Atomic bomb experience.* The atomic bomb explosions over Hiroshima and Nagasaki brought widespread destruction to these cities. Blast and fire caused most of the casualties, but about 15 to 20 per cent were caused by the gamma and neutron radiations emitted during the explosions. In 1946 the United States established in Japan the Atomic Bomb Casualty Commission, which has studied the immediate and the long-term effects of radiation from the bombs on the populations of both cities; the findings have been of great value in expanding knowledge on this subject.

34. *Analogous effects produced in animals.* The discovery that X-rays could produce changes in human tissues led investigators to study the effects of radiation on animals. As a result, it was established that radiation produces effects in animals similar to those observed in man and it thus became possible to make an experimental approach to the problem of radiation hazards. The knowledge thus gained has been drawn on freely in this report.

Factors Affecting the Severity of Radiation Injury

35. The harmful effects of radiation can be divided into those developing within a few weeks of exposure and those developing some considerable time, perhaps many years, afterwards. Illnesses which develop within a few weeks are sudden in onset and run an acute course, whereas those occurring some years after exposure develop insidiously.

36. The severity of radiation injury in any particular instance is determined by the interplay of several factors: the type and dose of radiation received, the duration of the period of exposure, the extent and part of the body which has been irradiated, and also the age of the person exposed.

The dose of radiation received

37. If the dose of radiation is a large one and is received by the whole body in the space of a few minutes, a severe and possibly fatal illness is likely to develop within a few hours, and certainly within a few weeks, of exposure. Some of those who survive this early illness may die several years later from one of the delayed effects of radiation, such as anaemia or leukaemia. Exposure of the whole body to smaller doses of radiation, over a period of months or years, will not cause the early illness, but there may still be a slightly increased risk of death from the delayed effects in later years.

The extent of the body irradiated

38. On the other hand, if only a fraction of the whole body is irradiated, as in radiotherapy, immediate general effects are rare, although some patients may develop a mild form of the early illness, known as radiation sickness. It is often necessary to give a large dose locally and there may be local reaction in the irradiated area with temporary reddening of the skin or blistering similar to that which occurs in sunburn. Delayed local effects

that may occur in these patients are scarring, less commonly necrosis and rarely the later development of cancer in the irradiated tissues. It is now apparent that there may be delayed general effects, a small proportion of patients in later years developing anaemia or leukaemia.

The part of the body irradiated

39. Experience has shown that there is a difference in the general effects of radiation according to the part of the body which is irradiated. Even quite a large dose of radiation given to a portion of a limb will usually produce no general ill effects whereas a similar dose directed to an equally large volume of tissue in the upper abdomen, for example, may produce severe immediate illness.

The type of radiation

40. The severity of effect produced by radiation may also depend to some extent upon the type of radiation concerned, since radiations differ in their powers of penetration and in their destructive effects. For example, fast neutrons are about ten times more potent than X- or gamma rays in causing cataract in the lens of the eye, although these three forms of radiation differ very little in their capacity to cause the early acute form of illness.

The age of the individual exposed

41. It has long been known to radiotherapists that young children are more likely than adults to develop reactions after irradiation. Further evidence on this point comes from a recent report on the inhabitants of the Marshall Islands, who were exposed to radioactive fall-out after the thermonuclear test explosion in that area of the Pacific Ocean in the spring of 1954. A consistently greater fall in the number of white corpuscles in the blood occurred among children than among adults, and a similar age-difference in response was noted also in regard to loss of hair.

The frequency of radiation effects

42. Reasonably good estimates have been made of the numbers likely to develop the acute illness under varying conditions of whole-body irradiation. Thus, every member of a population receiving a single whole-body dose of 500 r of gamma-rays would become ill shortly afterwards; if the dose were 150 r, only about half would do so; and, if it were of the order of 50 r, sickness would be extremely rare. It is much more difficult to assess the proportion likely to suffer from the delayed effects; all that can be said with certainty is that it would be small.

The Early Effects of Exposure to Radiation

43. The following description of the effects of a single heavy dose of gamma rays to the whole body is based on observation of the bomb-victims in Nagasaki and Hiroshima. It must be repeated that, in peacetime, exposure at this level could result only from an accident which would rarely, if ever, occur and that, even then, only those in the immediate vicinity of the disaster would be affected.

Effects of heavy dosage

44. The first effect of exposure of the whole body to a heavy dose of gamma rays of the order of 500 r is a sensation of nausea developing suddenly and soon followed by vomiting and sometimes by diarrhoea. In some people, these symptoms develop within half an hour of exposure; in others, they may not appear for several hours. Usually, they disappear after two to three days. In a small proportion of cases, however, the symptoms

persist; vomiting and diarrhoea increase in intensity; exhaustion, fever, and perhaps delirium follow; and death may occur a week or so after exposure.

45. Those who recover from the phase of sickness and diarrhoea may feel fairly well, although examination of the blood will reveal a fall in the number of white cells. Between the second and fourth weeks, however, a new series of ailments, preceded by gradually increasing malaise, will appear in some of those exposed. The first sign of these developments is likely to be partial or complete loss of hair. Then, from about the third week onwards, small haemorrhages will be noticed in the skin and in the mucous membranes of the mouth, which will be associated with a tendency to bruise easily and to bleed from the gums. At the same time, ulcerations will develop in the mouth and throat, and similar ulceration occurring in the bowels will cause a renewal of the diarrhoea. Soon, the patient will be gravely ill, with complete loss of appetite, loss of weight, and sustained high fever. Feeding by mouth will become impossible, and healing wounds will break down and become infected.

46. At this stage, the number of red cells in the blood is below normal, and this anaemia will increase progressively until the fourth or fifth week after exposure. The fall in the number of white blood cells, noted during the first two days after exposure, will have progressed during the intervening symptomless period, and will by now be reaching its full extent. The changes in the blood-count seriously impair the ability to combat infection, and evidence from Nagasaki and Hiroshima shows that infections of all kinds were rife among the victims of the bomb. Many of those affected die at this stage and, in those who survive, recovery may be slow and convalescence prolonged; even when recovery appears to be established, death may occur suddenly from an infection which in a healthy person would have only trivial results.

Effects of lighter dosage

47. The radiation effects described above are the most severe which can follow a single whole-body dose of 500 r of gamma rays and still allow some hope of survival; but at least half of a population so exposed would die. With smaller doses, fewer people would develop symptoms and the illness would become correspondingly less severe; thus, with a dose of 100 r, not more than about 15 per cent of the exposed population would be affected, the illness would be comparatively mild, and very few, if any, would die.

Effects of exposure to 'fall-out' in the vicinity of an explosion

48. The radiations considered above have been those occurring within one minute of the detonation of a nuclear weapon. These radiations have been called the 'prompt' radiations to distinguish them from those emitted by the radioactive dust, or fall-out, which settles over a wide area in the vicinity of an explosion. The fall-out may itself be active enough to cause radiation illness of a type similar to that described above and, in addition, it may contaminate and damage the skin with which it comes in contact.

49. Following the firing of a thermonuclear weapon in the region of the Marshall Islands, the fall-out on one island was so heavy that it was compared to snow, and the inhabitants received an estimated average whole-body dose of 175 r. This fall-out did not cause any deaths, but it did produce a mild illness with early sickness and diarrhoea, a fall in the number of cells in the blood, loss of hair, and some ulceration of the skin contaminated by radioactive material. The skin lesions, caused largely by the higher local

dose of beta-radiation emitted by the fall-out, appeared about two weeks after exposure on those parts of the body which had not been protected by clothing, and took the form of spotted areas of increased pigmentation, from most of which the skin peeled off as if it had been sunburnt. In about 20 per cent of cases, deeper ulceration of the skin occurred but all wounds healed satisfactorily.

Relationship between dose and incidence of effects

50. For the purposes of assessing risk and defining standards of safety, it is necessary to know the nature of the relationship between the dose of radiation and the effect induced. This relationship may be a simple linear one in which the incidence of the particular disease increases strictly in proportion to the dose received, or it may be a curvilinear one in which, with each successive and equal increment in dose, the incidence increases not by an equal but by a progressively greater amount. All the evidence suggests that the relation between dosage and radiation effects occurring within a few weeks of exposure is of the latter type, and that the curve shows a 'threshold' level, implying that a certain quantity of radiation must be exceeded before these particular effects are produced.

The Delayed Effects of Exposure to Radiation

51. Delayed effects of radiation which have been observed locally in tissues heavily irradiated are atrophy and fibrosis of the skin and underlying soft tissues, and sudden breakdown or necrosis of tissues such as bone and cartilage. In rare instances cancer has subsequently developed in the damaged tissues. Cataract has occurred if the lens of the eye has been irradiated. The delayed general effects of radiation which are known, are the development of severe anaemias and leukaemia; in addition, evidence is beginning to accumulate from observations made on animals that irradiation may cause some shortening of the normal life-span. In our report we have dealt in considerable detail with leukaemia, because experience in Japan following the atomic bomb explosions in 1945, and the results of our own investigation on the incidence of leukaemia among irradiated patients, have provided more precise information on the effects of different levels of exposure than is available for any other of the delayed effects.

52. The knowledge that long-term effects may be produced by radiation is in itself an insufficient basis for assessing the risk that any of them will develop as a result of a particular dose. For this purpose, it is necessary to estimate, from national mortality statistics, the incidence of the condition in the absence of exposure to radiation additional to that from natural sources, and then to compare this figure with the incidence of the same condition in a population that has been exposed to radiation. If an increase is demonstrated, the frequency with which the condition develops at different levels of radiation dose must be determined, and the relationship between the dose and the incidence of the disease must be evaluated. Only then is it possible to assess the hazards, if any, associated with the different uses of radiation.

INDUCTION OF LEUKAEMIA

53. Leukaemia is a disease in which uncontrolled over-production of the white blood-cells occurs. It is at present invariably fatal, although some forms may run a protracted course over many years. Several kinds of leukaemia are described according to the type of cell mainly affected. Usually, there is an increase in the number of the affected cells in the blood, associated with the appearance of immature forms of the cell in question. In some cases, however, the numbers in the blood may fall below normal

through failure to liberate the cells from their site of formation in the bone marrow; the disease is then known as aleukaemic leukaemia.

54. In many countries the death rates from leukaemia have shown a steady rise in recent years. In 1920 the crude annual death rate from this condition for both sexes in England and Wales, for example, was 11 per million persons; in 1954 it was 49 per million. Some of this rise has undoubtedly been due to an improvement in diagnosis but it seems probable that this is not the whole explanation and that, for a reason as yet unknown, there has been a real increase in the national death rate from leukaemia.

55. It is known that leukaemia may be induced in animals as a result of exposure to radiation. Case reports have appeared from time to time of patients who have developed leukaemia after exposure to radiation for the treatment of various diseases, and there have also been a number of reports of radiologists dying from leukaemia. Such isolated reports do not of themselves prove that the relationship is one of cause and effect, but the matter has now been put beyond doubt by a series of recent observations on the incidence of leukaemia under conditions in which an estimate could be made of the degree of exposure to radiation.

Leukaemia following a single exposure: atomic bomb explosions

56. The most recent information, for which we have to thank the United States National Research Council, covers all cases of leukaemia recorded by the Atomic Bomb Casualty Commission in Nagasaki and Hiroshima between January, 1947, and August, 1955. Vital statistics allow an estimate to be made of the number of cases of leukaemia that would have been expected to occur over a similar period in a Japanese population not exposed to radiation from the bombs but otherwise comparable to the surviving populations of Nagasaki and Hiroshima. Calculations have been made for the combined totals of the survivors of the explosions in both cities (Appendix A).

57. During the eight years from 1947 to 1954, about 25 deaths from leukaemia would have been expected in an unexposed Japanese population of the same size and having the same age and sex distribution as the combined populations of survivors from both cities. Over the same period, however, 91 proven and 14 suspected cases have been recorded among those present at the time of the explosion and still resident in one or other city at the time of diagnosis. The difference between the expected and the observed number of cases is so great that it is most unlikely to be due to chance.

58. The difference between the numbers expected and those observed becomes even greater if the most heavily irradiated survivors are considered separately. Only for Hiroshima are adequate details available of the distances from the centre of the explosion at which the individual survivors had been exposed. In the absence of radiation, it is unlikely that even one case would have occurred among the number of survivors less than 1,000 metres distant, yet 15 cases have been found. Further, there is a much higher incidence among those who developed the early acute illness than among those who had, at the most, only mild symptoms.

59. An examination of the incidence of leukaemia in relation to the distance from the explosion has been made for the survivors in Hiroshima, where the concentric distribution of the radiation was not affected to the same degree as in Nagasaki by the irregular distribution of the radio-active fall-out. The dose from the prompt radiation decreases as the distance from the explosion increases. In survivors who were 2,000 metres distant

or more, the incidence during the period January, 1947, to August, 1955, was about 2 cases in every 10,000 persons. Among those between 1,500 and 2,000 metres distant, the incidence was about 3 to 4 cases per 10,000 persons, and for those at the shorter distances of between 1,000 and 1,500 metres and under 1,000 metres it was respectively about 28 and 128.

60. To make an accurate estimate of the relationship between the dose of radiation and the incidence of the disease, one would have to substitute doses expressed in roentgen units for the distances from the centre of the explosion. It has not been possible to obtain reliable estimates of these doses, which should include not only the contribution from the gamma rays but also that from the neutrons emitted by the explosion and that from the radioactive fall-out. Tentative estimates of the gamma ray dose received by people standing in the open can be made from the information published in 1950 by the United States authorities in 'The Effects of Atomic Weapons'. These estimates suggest that the dose at under 1,000 metres would not be less than 1,400r, and at 1,250 metres about 350r. At 1,750 metres it would be about 50r, and at 2,000 metres about 8r. As a dose of 1,400r or more would kill everyone exposed to it, survivors who were within 1,000 metres of the explosion must have been heavily protected. An unknown proportion of the survivors at all the other distances must also have been protected to some extent because they were either indoors or, if outside, shielded by buildings. For this reason, it is not possible to indicate with any great confidence the average levels of dose received by survivors at different distances from the bomb and, in view of the uncertainty about the actual doses received by the exposed population, one cannot infer with certainty whether the relationship between dose and the incidence of leukaemia is a curvilinear or a linear one.

61. For the Japanese cases which occurred up to the end of 1954, the average length of the period between exposure to the bomb and the first appearance of symptoms was about 6 years. It is clearly important to determine whether there has been any tendency for cases to occur less frequently in subsequent years. The morbidity rate has therefore been examined year by year in both Hiroshima and Nagasaki, and it has been found that the recorded incidence has remained approximately constant in Hiroshima in the period 1948 to 1954, and in Nagasaki in the period 1950 to 1954 (Appendix A). This finding suggests that there is no sharply-defined peak year of occurrence, but that with this type of exposure the incidence of leukaemia rises, after a variable latent period, and then remains approximately constant up to at least the ninth year.

Leukaemia following repeated exposures: radiotherapy

62. Before 1955, there had been a report of leukaemia developing in two patients given X-ray treatment for ankylosing spondylitis. In 1955, two further publications directed attention to this possibility, and another reported the occurrence of leukaemia in young children who had been given X-ray treatment to the chest in infancy for suspected enlargement of the thymus gland. In an attempt to obtain further evidence on the occurrence of leukaemia as a delayed effect of irradiation, and in particular on the relationship between the dose received and the incidence of the disease, we have sponsored a survey of patients treated for ankylosing spondylitis with radiation.

63. Ankylosing spondylitis is a disease which affects chiefly the joints of the spine, and to a less extent other joints, particularly those of the pelvis and the shoulders. It usually starts in early adult life and is about six times more frequent in men than in women. It causes severe pain and reduced mobility and, unless treatment is given, the affected joints may gradually lose their freedom of movement and the back become progressively stiffer. In

93299 O—57—pt. 2——36

severe cases all spinal movement is lost, chest expansion is greatly diminished, and the movements of other major joints restricted. The popular description, 'poker back', is a very apt one.

64. Some patients with this condition are benefited by X-ray treatment, which is given to relieve pain and increase mobility and which may permanently halt the progress of the disease. As treatment usually takes the form of irradiation of the whole spine in one course of radiotherapy, it involves exposing a large section of the body directly to the X-rays. In some patients one course of treatment does not suffice, and further courses have to be given, either to the spine or to the major joints, or to both. Indeed, this group of patients was chosen for our investigation because the treatment is so extensive that it more nearly approaches whole-body irradiation than that given for any other non-malignant condition.

65. An analysis has been made of the hospital records of between 13,000 and 14,000 patients, all of whom had been treated with X-rays at some time during the twenty-year period 1935 to 1954. Thirty-eight of these patients developed leukaemia, an incidence of only about one-third of one per cent; yet calculations based on the national death rates over the same period show that even this low incidence is about ten times greater than would have been expected in the absence of irradiation. The possibility of such a difference being due to chance is so remote that we shall ignore it.

66. Caution is necessary, however, in interpreting this finding. It is not possible to conclude immediately that the increased number of deaths from leukaemia is related to the X-ray treatment, in the way that the increased death rates among previously healthy people in Hiroshima and Nagasaki can be attributed to exposure to the radiations from the bombs. The possibility has to be considered that death from leukaemia would, even in the absence of treatment by irradiation, be a more frequent occurrence among sufferers from ankylosing spondylitis than among the normal population, or alternatively that ankylosing spondylitis in some way increases a patient's susceptibility to irradiation.

67. By courtesy of the Ministry of Pensions and National Insurance, it has been possible to examine the records of a group of about 400 male patients with ankylosing spondylitis who had never at any time been treated with X-rays. The fact that no increased incidence of leukaemia was found in this group suggests that ankylosing spondylitis does not of itself predispose a patient to the development of leukaemia. To confirm this point, it would be necessary to examine the records of a much larger group of unirradiated patients; X-ray treatment is, however, so widely used for ankylosing spondylitis that it may be difficult to do this.

68. Clear evidence was, however, found in our main investigation for the existence of a relationship between the dose of radiation and the incidence of leukaemia. The dose was estimated in two different ways, firstly by calculating the total amount of energy absorbed in the whole body, and secondly by calculating the dose of radiation received in certain parts of the bone marrow. The first method demonstrated a curvilinear relationship between the incidence of leukaemia and the radiation dose, whereas the second method resulted in a linear relationship. Fortunately, over the range of doses likely to be met with in ordinary civil conditions, the difference between the two results is negligible. The theoretical implications of the two possible relationships are, however, very different and important and point the way to considerable future research. The data upon which the findings are based are summarised in Appendix B.

69. The average length of time between the first exposure to X-rays and the diagnosis of leukaemia was about six years. This period cannot be directly compared with that observed in the Japanese cases, as many of the patients had had several courses of radiation before leukaemia was diagnosed, and it is not known which particular course was the effective one or whether all the courses may not, to some degree, have affected the development of the disease. Nevertheless, it may be concluded from both series of cases that the latent period for radiation-induced leukaemia is shorter than for radiation-induced cancers.

Leukaemia following chronic exposure

70. We have no precise knowledge of the incidence of leukaemia under conditions of chronic exposure. It has been reported that, relative to the numbers at risk, there are about nine times as many deaths from leukaemia among American radiologists as among other American physicians. This figure is based on a study of the obituary notices published in the Journal of the American Medical Association from 1929 to 1948, in which both the professional occupation and the cause of death are usually reported. In about a quarter of the notices, however, the cause of death was not reported and thus a bias may have been introduced into the results of the study. A review of all the published papers on this subject shows that there may well be an increased death rate from leukaemia among American physicians as a whole, compared with the general population, and in particular among American radiologists, but it is not possible to estimate the extent of the increase with any certainty.

General conclusions on the induction of leukaemia

71. The results of the investigations carried out by the Atomic Bomb Casualty Commission in Japan, and of our own study of the occurrence of leukaemia in patients with ankylosing spondylitis, leave no doubt that ionizing radiations can induce leukaemia in man, and that the average latent period between exposure and the development of the disease is only a few years. In neither of these situations were the conditions of exposure similar to those of persons engaged in work associated with a possible radiation hazard. Those exposed occupationally tend to receive radiation in small doses over long periods, and it is not yet known whether the dose-response relationship based on short periods of heavy exposure is directly applicable to such conditions.

INDUCTION OF CANCERS

72. The evidence for the induction of cancers by radiation consists chiefly of reports of the occurrence of cases under circumstances which make it reasonable to suppose that some at least were radiation-induced, and of the apparently increased frequency of a particular type of cancer, itself rare in the normal population, in persons exposed to heavy doses of radiation. Most of the information comes from the case-records of patients treated with radiotherapy and from those of workers in certain special occupations who in the past received very heavy doses of radiation in the course of their work. It is noteworthy that tumours following radiotherapy tend to develop in tissue already severely damaged by radiation, and that, compared with leukaemia, a much longer period—up to 20 years or more—usually elapses between the first exposure to radiation and the clinical appearance of the disease.

Cancer of the lung

73. The mines of Schneeberg and Joachimsthal are rich in a variety of ores and, since the latter part of the last century, pitchblende, an ore containing radium and other radioactive elements, has been extensively worked there. It had long been known that the miners were liable to die in middle-life from a respiratory disease locally named 'mountain sickness'. It is now recognised that this condition is one of cancer of the lung and it is generally accepted that there is a strong connexion between the excessive mortality from this disease and the high radioactive content of the air of the mines. Investigations have suggested that, up to 1939, nearly one-half of the miners who had died had contracted lung cancer.

74. The first decay-product of radium is a gas, radon, which in its turn disintegrates, giving rise to a series of products, all of which are solids. Radon, being a gas, diffuses through the rocks containing the radium ore, and escapes into the atmosphere of the mines. The inhalation of radon is known to constitute a serious hazard, and the International Commission on Radiological Protection has advised that the concentration of this gas in the inspired air should not exceed 0·0001 microcuries per litre. A series of measurements of the radon content of the air of the mines, made between 1924 and 1939, showed that the concentration of radon must then have been on the average about thirty times greater than the maximum permissible level since laid down. The serious hazard incurred in breathing such an atmosphere comes, not only from the radon itself but also from its solid daughter-products which, being attached to dust particles in the atmosphere, may be retained in the chest and may irradiate the tissues of the lungs for long periods.

75. The average latent period for the induction of lung cancer in these miners was about 17 years, and calculations have shown that the dose to the lungs during this period would have been equivalent to about 1,000 r. This calculation assumes that the radiation dose is spread evenly over the lungs, but it may well be that some areas of the lung, depending on the sizes of the radioactively-charged dust particles which are inhaled, may be subjected to doses of more than 10,000 r over a whole working life. It is consistent with other knowledge that tumours could be induced under these conditions, particularly when it is remembered that radium itself and many of its daughter-products emit alpha particles with high biological efficiency.

76. The only conditions in which an increased incidence of lung tumours has been observed in association with radiation are those in which there is an increased risk of inhaling radon and the other daughter-products of radium. In theory, however, the inhalation of radioactive material in particulate form, either as a result of fall-out from nuclear weapon explosions or in the vicinity of nuclear reactors, could lead to the accumulation of a high radiation dose within the lungs. Such particles would not be uniformly distributed within the lungs but would tend to aggregate on discrete small areas of the bronchi, which would thus be subjected to a high radiation dose, with the result that in the long run lung cancers might be produced in some people. In this country appropriate measures are always taken to eliminate the hazard in the vicinity of nuclear reactors, and it would be extremely unlikely to occur as a result of fall-out except in conditions of actual warfare. There is no evidence that external irradiation by X- or gamma rays can cause lung tumours in man.

Cancer of the bones and joints

77. Radium and the daughter-products of thorium, when assimilated into the body, tend to be held for long periods of time in the bones where, if

in sufficient concentration, they may give rise to local destruction and disease. A number of artificially produced radioactive isotopes, of which the most important are strontium and plutonium, also show this predilection for bone. Radioactive strontium exists in several forms, one, strontium 89, having a half-life of 53 days and another, strontium 90, of 28 years, while the half-life of plutonium 239 is about 24,000 years. A warning of the potential danger from these artificial elements is given by past experience of the effects of the natural elements radium, mesothorium and radiothorium after they have gained entrance to the body and become fixed in bone (Appendix N).

78. Our knowledge of these effects comes mainly from the case-records of former workers in the luminising industry and of a group of patients given radium compounds internally in the course of treatment. Stringent controls are now enforced in the luminising industry to protect the workers, and the prescription of radioactive substances for treatment has been controlled by legislation.

79. Since 1925 there have been many reports of illness and death occurring among a group of workers engaged in the painting of watch and clock dials with luminous paint, most of whom had been in the industry during the period from 1916 to 1924. Luminous paint is compounded of zinc sulphide and radium, and, formerly, varying mixtures of radium, mesothorium and radiothorium were also used. It was customary for dial painters to apply their paint with fine brushes, the points of which they 'tipped' between their lips before painting. In this way they swallowed radioactive material, some of which became lodged in the skeleton. If large amounts were swallowed, death sometimes occurred, within about three years, from severe anaemia, haemorrhages, and infections, particularly of the bones of the jaw. Those who had ingested smaller quantities of paint often developed cystic and necrotic changes in the bones which might cause 'rheumatic' pains or fractures. Occasionally, these changes progressed and cancer of the bones appeared. Such tumours usually developed more than fifteen years after the first exposure to the hazard.

80. Similar effects have occurred in patients given radium compounds internally for the treatment of mental disease or for various rheumatic and other affections, and in people who, for quasi-medicinal reasons, have consumed large amounts of 'radioactive water'. In animals strontium 90 has been shown to produce similar biological effects.

81. It is possible to estimate the amount of radium in the body of a living person, if there is good evidence that no other radioactive element is present in addition to the normal components of the body. Measurements carried out on those who have been exposed to unknown mixtures, such as luminous compounds, are difficult to interpret. So far, no person is known to have developed radiation-induced bone cancer who had less than 3·6 microcuries of radium in his body, unless either mesothorium or radiothorium was also present; the lowest radium content, in the presence of one or other of these elements, has been 0·52 microcurie at the time of appearance of the tumour. On the other hand, it seems certain that early non-cancerous cystic changes in bones have developed with a body-content of as little as 0·4 microcurie of radium alone. These amounts of radium are to be contrasted with the maximum permissible level for body radium, which, as laid down by the International Commission on Radiological Protection, is 0·1 microcurie.

82. Bone cancer has also been reported after the use of X-rays in the treatment of non-malignant bone tumours and some infections. Such cancers have occurred only after very heavy doses of radiation and have originated

in the area of the body treated. The risk of the development of bone cancer at the levels of X- or gamma radiation experienced under modern occupational conditions is insignificant.

Cancer of the skin

83. Cancer of the skin was the earliest form of radiation-induced tumour to be described in man. Radiation dermatitis of the hands, forearms and face was common among the early radiologists and radiological technicians, and cancer often occurred in the damaged skin. By 1911 no fewer than 54 cases had been described; the occurrence of these tumours diminished as radiologists learned to take the necessary precautions.

84. Since the early part of the century, records have accumulated of the occurrence of skin cancers following X-ray or radium treatment. In some instances, these tumours have followed the injudicious use of X-rays for mild skin affections, or even for the removal of facial hair. The latent periods have usually been long, ranging in a recently reported series of 13 cases from 12 to 56 years, with an average of 33 years. Although it is usually impossible to make any accurate retrospective assessment of the doses of radiation received, the severity of damage to the skin suggests that, in these cases, they must have been of the order of several thousands of roentgens.

Cancer of the thyroid gland, the pharynx and the larynx

85. A number of cases of cancer of the thyroid gland have been reported among children, some years after they had been given X-ray treatment for conditions including suspected enlargement of the thymus gland, bronchitis, infected tonsils and adenoids, and enlarged glands in the neck. In many instances, the children were less than one year old when irradiated. In a series of cases irradiated for suspected enlargement of the thymus gland, the average latent period between irradiation and the establishment of the diagnosis of cancer of the thyroid gland was only about 7 years. Perhaps the most important feature of these cases is the comparatively small dose of radiation responsible for induction of the tumour, in contrast to the large doses associated with the induction of cancer in adults; cancer of the thyroid gland has developed in a child after a recorded dose as low as 250 r. It is possible that hormonal factors may be involved in addition to the direct effect of irradiation.

86. A few reports have drawn attention to the development, many years later, of cancers of the pharynx and larynx in patients who have had X-ray treatment for such conditions as tuberculous glands of the neck. The latent period is long, averaging about 20 years, and periods of more than 30 years have been recorded. In most cases, the irradiation was given in the early days of radiotherapy and there is practically no information available about the size of the radiation doses that were employed.

EFFECTS ON THE BLOOD OTHER THAN LEUKAEMIA

87. Observations have shown that a fall in the numbers of red cells, white cells and platelets in the blood may occur in persons exposed to radiation in the course of their work. There is little direct information on the dose-response relationships, but it seems possible that, even with whole-body doses of gamma rays as low as 1 r per week, slight changes can occur in the white-cell count of especially susceptible people. Certainly, with doses much in excess of 1 r per week, a general depression occurs in the white blood cell count. A reduction in the numbers of red cells and platelets may occur at a later stage, and in some persons continued exposure may lead to severe degrees of anaemia.

Aplastic anaemia

88. If not detected in time, radiation-induced anaemias may endanger life, particularly when the red bone-marrow is itself so severely damaged that the red-cell deficiency cannot be made good by the production of new cells; this condition is known as 'aplastic anaemia'. The diagnosis is not easy to make, and the condition can easily be confused with aleukaemic leukaemia unless a full examination of the bone marrow is carried out. This diagnostic difficulty was encountered during the investigation of leukaemia among patients treated with X-rays for ankylosing spondylitis. Particular attention was paid to deaths reported as being due to aplastic anaemia but, when these cases were fully investigated, evidence was found that a number were, in fact, aleukaemic leukaemia; eventually, only four deaths could with any certainty be ascribed to aplastic anaemia out of a total of some 50 deaths from leukaemia, aplastic anaemia and allied diseases combined. Similarly, only six cases of aplastic anaemia were reported from Nagasaki, compared with over 40 cases of leukaemia in the same city. It seems clear, therefore, that aplastic anaemia is a rarer delayed effect of radiation than leukaemia.

INDUCTION OF CATARACT

89. The term 'cataract' implies an opacity in the normally transparent lens of the eye, varying from a tiny granule which does not cause any definite impairment of vision, and which may disappear, to a large plaque resulting in blindness. It has been known for some time that exposure of the eye to X-rays can lead to cataract formation, but the large doses which appear to be necessary for its induction are only likely to occur under very unusual conditions. For all practical purposes, therefore, the production of cataract by X-rays is not an occupational hazard, although it was discovered in 1948 that the condition had developed among a group of physicists exposed to neutron irradiation during the operation of a cyclotron.

90. In the following year there were reports from Japan of an increased incidence of cataract in the populations of Hiroshima and Nagasaki. The extent of the increase cannot be determined with precision, but it is significant that, of 98 cases of cataract among survivors of the Hiroshima explosion, 85 occurred in persons who were within 1,000 metres of the centre of the explosion and would thus have been subjected to neutron- as well as gamma-irradiation. Confirmatory evidence of the high dosage which they had received is provided by the fact that most of them had suffered epilation of the scalp and that two subsequently developed leukaemia.

EFFECTS ON THE SKIN OTHER THAN CANCER

91. In the paragraphs dealing with the induction of skin cancers by irradiation, it was noted that cancers develop mainly in skin which has been subjected to such heavy doses of radiation as to be obviously damaged. Most of our knowledge of the less serious delayed effects on the skin has been obtained from observation of the results of therapeutic irradiation with X-rays, during which the skin may be exposed to large doses of radiation directed to underlying tissues. With doses of 1,500 r or more, a certain amount of permanent skin-damage is likely to occur, but it will not be particularly severe unless a large area has been irradiated. Larger doses, however, say of 4,000 r or more, are often followed by obvious skin-damage, the texture becoming thinner, and the surface being usually covered with dilated blood vessels. In such cases, the skin may be very sensitive and prone to infection, and it is in this type of damaged skin that radiation-induced tumours are most likely to develop.

92. The hair follicles and glands of the skin may also be affected by radiation. A dose of the order of 300 to 400 r will cause temporary loss of hair, and with higher doses, perhaps 700 r or more, hair-loss may be permanent. It is a common finding that, owing to the destruction of the sweat glands, heavily irradiated skin permanently loses its ability to sweat. After doses of the order of 1,500 r, the sebaceous glands are destroyed and the skin loses its normal greasy texture.

EFFECTS ON THE KIDNEY AND LUNG

93. It has been reported that therapeutic doses of X-rays to the region of the kidneys may affect their function and lead to the development of high blood pressure which may prove fatal. The damage described has followed the treatment of certain rare tumours with large doses of radiation and it is unlikely that such effects will occur under other conditions of exposure. It has also been reported that pneumonitis, sometimes fatal, has followed radiotherapy directed towards the chest.

SHORTENING OF THE LIFE-SPAN

94. A number of reports based on observations made on animals suggest that exposure to ionizing radiations may lead to a reduction in the expectation of life. No evidence has yet been published that this occurs in man.

The Effects of Exposure to Radiation during Pregnancy

Abortion and stillbirth

95. After heavy doses of radiation, a pregnant woman may miscarry or give birth to a stillborn child. Information from the Atomic Bomb Casualty Commission shows that in Hiroshima and Nagasaki there were higher abortion and stillbirth rates among pregnant women near the explosion than among those at greater distances. Of 98 pregnant women in Nagasaki who were within 2,000 metres of the centre of the explosion, about 23 per cent of those who had severe radiation illness miscarried, in comparison with only about 4 per cent of those who did not develop any severe illness, and with about 3 per cent of women who were between 4,000 and 5,000 metres distant. It is apparent that abortion and stillbirth as a result of irradiation during pregnancy do not constitute a problem unless the dose of radiation is large.

Effects on the children of women irradiated during pregnancy

96. There is considerable evidence, both from the case records of patients treated with radiotherapy and from reports published by the Atomic Bomb Casualty Commission, that heavy irradiation of pregnant women can lead to the birth of children who are either abnormal at birth or who later develop in an abnormal way. The case records of women therapeutically irradiated during pregnancy describe a number of different developmental abnormalities in their children, the most striking of which is the condition known as 'microcephaly'; one such case was found during the course of our investigation of patients treated by X-rays for ankylosing spondylitis. The underlying cause of this condition is a partial failure of the development of the brain, as a result of which the head is smaller than that of a normal baby. All grades of the condition exist, ranging from the most severe, in which the child usually has to be maintained in a mental institution, to others in which there is only slight impairment of development and mental powers.

97. There are published records of eleven mentally-retarded children in Nagasaki and Hiroshima who were exposed before birth at a distance of between 700 and 1,200 metres from the centre of the explosion. Ten of the mothers of these children suffered acutely from the effects of radiation, and the eleventh probably did so. The head circumferences of all eleven children were appreciably less than those of unirradiated Japanese children of the same age-group and, in the cases among Nagasaki children, smaller than those of children exposed before birth at distances of between 4,000 and 5,000 metres from the explosion, where the dose of prompt radiation would have been less than 1 r. The evidence from Hiroshima suggests that children irradiated between the twelfth and eighteenth weeks of intra-uterine life are more likely to develop microcephaly than children irradiated either before or after this period.

The Effect on Fertility of Exposure to Radiation

Permanent sterility

98. It is well-established that irradiation may reduce the fertility of men and women, and even render them permanently sterile. In men, a single dose of 500 r to the testes would probably produce permanent sterility. The dose to the ovaries likely to produce the same result in women would depend to some extent upon the age of the woman concerned; a woman nearing the end of her reproductive life would require a smaller dose, about 300 r, than a woman in her early reproductive years. These levels of dose are so high that, if they were received in the course of whole-body irradiation, the individual would develop the early acute illness already described. It is extremely unlikely, therefore, that permanent sterility would be induced in any one accidentally exposed to a large whole-body dose of radiation, unless the acute illness had been manifest.

99. Under modern conditions of occupational exposure, for example among radiologists and radiographers, there is no evidence of any impairment of fertility. Furthermore, there is no suggestion that female radiographers suffer from radiation-induced menstrual disturbances which might be accompanied by diminished fertility.

CHAPTER IV

THE GENETIC EFFECTS OF RADIATION

Introduction

100. Nowhere in our report have we been more conscious of the difficulties of the task which we have undertaken, and of the limitations of the knowledge at our disposal, than in considering the genetic effects of radiation. The established scientific evidence in this field provides but an insecure basis on which to frame answers to the many important questions that are now being asked. Consequently we have been forced to make many assumptions of questionable validity and our conclusions must be regarded as provisional and treated with a measure of reserve. An essential part of future studies will be the collection of more detailed vital statistics. Moreover, it must be realised that genetic studies inevitably tend to be slow and that sufficient knowledge on which to base firm conclusions will be accumulated only after many years of intensified fundamental research.

The Material Basis of Heredity

101. In man and other sexually reproducing animals, every individual arises from a single living cell, which is formed by the fusion of two germ cells, an egg cell from the mother and a sperm cell from the father. Soon after it is fertilised, the egg cell divides into two; each of these divides again, to give a total of four, and this process is repeated until there are enough cells to give rise to all the organs and tissues of the body, among them the sex glands from which in time new germ cells will be formed.

Chromosomes and genes

102. Each cell contains within it a nucleus whose essential component is a number of microscopic thread-like structures, the chromosomes. These are aggregates of sub-microscopic particles—the genes—which determine the hereditary nature of the individual. The total number of genes in a cell is not known with any accuracy but it is certainly high, perhaps thousands or even tens of thousands in a human cell. Each chromosome carries a large number of them arranged in order along its length, so that each gene has its own special place, or locus, in a particular chromosome.

Cell division

103. The nucleus of each human germ cell carries 24 chromosomes, all of them different from one another. When egg and sperm come together, their nuclei also fuse, so that the fertilised egg contains a nucleus carrying 48 chromosomes constituting 24 pairs. The members of a pair, derived one from the mother via the egg and one from the father via the sperm, normally correspond to each other both in the gene loci which they carry and in the order in which these loci are arranged. When the fertilised egg, or any later cell in the body, is about to divide, a replica is first formed of each of the 48 chromosomes. This makes it possible for the two cells so produced to receive sets of chromosomes exactly like each other and like those of the parent cell. The cell divisions immediately preceding the formation of germ cells, however, follow a somewhat different pattern, which

results in the egg or sperm receiving only one member of each pair of chromosomes; thus the number that the egg or sperm contains is reduced to 24.

Gene mutation

104. In the normal course of events, each cell possesses a set of genes identical with those of the cell from which it is derived. Occasionally, however, a sudden change occurs in a gene, which is converted into a slightly different form. The altered form of the gene is spoken of as a new allele and the process of change is known as mutation. Once such a mutation has occurred, the gene is reproduced and passed on in the new form at all subsequent cell divisions. Thus, each locus can come to be represented in the population by a number of these variants or alleles.

Homozygotes and heterozygotes

105. Having but one chromosome of each kind, the germ cell carries only one allele at each gene locus, whereas the body cells, with a pair of each kind of chromosome, carry two alleles. These two alleles may or may not be exactly the same. An individual bearing two identical alleles is said to be homozygous at that particular locus; one with two different alleles is said to be heterozygous at the locus. A homozygous individual clearly must have received the same allele from each of his parents and he will pass it on to all his offspring. A heterozygous individual must have received different alleles from his two parents, and he will on the average pass on one of the two to half his offspring and the other to the other half. This sorting out of the genes when they are distributed to the offspring of a heterozygote is a direct result of the halving of the number of chromosomes during germ cell formation and is known as segregation.

Gene reassortment

106. If an individual is heterozygous for two or more loci, the process of segregation will result in his genes being reassorted into new combinations in his offspring. Thus, in the process of reproduction, the various alleles at the different loci are continually being reassorted into an immense variety of combinations, with the result that each person has a particular hereditary constitution not exactly like that of anyone else. Each of us is, in fact, genetically unique, with the exception of identical twins, who are produced when the fertilised egg—very early in its development—splits into two parts each of which gives rise to a complete individual.

Dominant and recessive alleles

107. Some alleles produce a noticeable effect only on those individuals who are homozygous for them. Such alleles and the characters which they determine are spoken of as recessive. Other alleles have some effect even when the individual is heterozygous, and the characters which these determine are described as dominant. Among the numerous genes which have been studied in man and other animals, all gradations are known between the extremes of fully recessive alleles, which have no effect at all on the heterozygote, and fully dominant ones which have as strong an effect on the heterozygote as on the homozygote.

108. A dominant allele which is being transmitted in a family will be manifest in every generation unless it dies out. A recessive allele, on the other hand, can be transmitted to later generations by an individual who shows no sign of carrying the allele in question. The character produced by such

a gene will appear from time to time in the population, in families where both parents carry the gene; this is especially likely to occur where there is a marriage between cousins.

Sex-linked genes

109. There is a special category of genes whose transmission is connected with the determination of sex. The sex of an individual is determined by one particular chromosome pair. In the female, both chromosomes of the pair are similar; in the male, one is of another type. Thus, the structure of the female sex chromosome pair can be represented as XX, that of the male as XY. Genes carried on these chromosomes are said to be sex-linked, but the Y chromosome, having few geni loci, has little effect on most hereditary characters. If a male contains an abnormal allele on his X chromosome, he will show its effect, even if the same allele situated on one of the two X chromosomes of a female would be recessive. If a recessive sex-linked gene is uncommon, it will occur only very rarely on both the X chromosomes of a female and the characteristics it produces will therefore not often be found in females. They will be commoner among males, who will be affected whenever their single X chromosome contains the allele. The apparently normal females can, however, transmit the chromosome carrying the affected gene to the next generation, and so act as carriers of the abnormality. The classical example of this type of condition is the disease haemophilia, which appears in males but is transmitted by apparently normal females.

Continuous variation

110. Not all gene differences have effects which are sufficiently distinct to be recognised by their segregation among the members of a family. As can be seen in human stature and intelligence, for example, some characteristics vary by continuous gradations over a wide range which is regarded as normal. Such characters are believed to be controlled by the combined action of a large number of genes, the effects of which are supplementary and each so small that they are not individually distinguishable.

Causes of mutation

111. Reference has already been made to the process of mutation by which one allele changes into another. We do not know all the factors which cause mutation. It is believed to be due sometimes to chance disturbance of the complex molecules which constitute the genes, and sometimes to external influences such as certain chemicals or natural background radiation. We shall discuss later the extent to which naturally occurring mutations are likely to be attributable to background radiation, but from observation of organisms other than man it is known that other causes can be important. Present evidence suggests that mutations, whatever their origin, are for the most part random changes not specifically related to the nature of the stimulus or to the needs of the individual.

Mutation rate

112. So far as is known, all genes are subject to mutation, and, over the population as a whole, mutation is continually occurring at a definite but very low rate (Appendix C). Factors influencing mutation increase the rates at which the genes change; they do not produce changes of a novel type. Most genes, if not all, are susceptible to such factors, though some may be affected more readily than others. No methods are yet known for stimulating the mutation of only one particular gene, or even of a small selected group of genes.

Mutation and natural selection

113. The hereditary variation found in human or other populations is the result of mutations which occurred in past generations. New alleles which cause abnormalities harmful to those who possess them tend to be eliminated from the population. Thus, a new dominant allele causing death before the reproductive age, or for some other reason preventing the individual from leaving descendants, is eliminated in one generation. Those with less drastic effects are eliminated with a speed related to the severity of the handicap which they impose. Recessive alleles, which give rise to harmful conditions only when they are in the homozygous state, are also eliminated, but very slowly, since the allele can continue to exist or to spread in the heterozygous state without contributing any significant handicap to the perpetuation of the line. Thus, in the case of both dominant and recessive harmful alleles, natural selection is constantly operating towards their removal from the population. Equally, it will operate even against genes whose effects are valuable to the individual during his own lifetime, if they reduce his chances of leaving offspring.

114. For alleles which increase the chances of leaving offspring the situation is the reverse. Those individuals in which these effects are manifest are more than ordinarily likely to propagate their kind, so that their descendants tend to become the predominant type. Many, but perhaps not all, of the genes which tend to increase fertility will also have effects which are useful in other ways to the individual in whom they are manifest; they can be considered as generally advantageous.

115. Between these clear-cut examples there are genes with every gradation of effect. The manifestations of genetic abnormality in the individual may vary from the trivial to the disastrous. The action of some genes is delayed until after the end of the reproductive period of life and they are therefore largely immune from the eliminating influence of natural selection. There are genes which are harmful whether the individual carrying them is homozygous or heterozygous; there are others which are advantageous to heterozygotes and harmful to homozygotes. The relative prevalence of any particular allele, in any particular population, can be understood only in the light of the relationship between the environment and the advantages or disadvantages of the condition to which the allele gives rise.

Genetic equilibrium

116. As natural selection is constantly operating towards the elimination of harmful genes from the population, the incidence of the conditions to which they give rise would steadily decrease, were it not that they are being replenished by the occurrence of new mutations. Their frequency will therefore tend to reach the level at which their loss by selection is balanced by new mutation. A state of genetic equilibrium has then been reached. This is the situation with regard to many of the more harmful abnormalities in man, the incidence of which remains relatively steady in the population despite the failure of those affected to leave normal numbers of offspring.

The general effects of increasing mutation rates

117. The above considerations suggest the broad qualitative effects which can be expected to follow an appreciable increase in mutation rates. At this present time, the advantageous alleles that have appeared in the past are already widespread and will have become part of the normal constitution of the population. An increase in the rate at which they are produced can therefore have little effect. The harmful alleles, on the other hand, have been restricted to a low incidence by the operation of natural selection. A

significant increase in the rate at which these are produced will therefore have a more easily detectable effect. The general inference is that increasing the mutation rate in a human population would have a relatively much greater effect upon the incidence of harmful than upon that of harmless or of advantageous hereditary traits.

Mutation and the adaptability of populations

118. Mutation provides the means by which the human race, through hundreds of thousands of years, has successfully adapted itself to its environment. There is no reason to believe that this adaptation has proceeded by sudden and conspicuous changes in human characteristics. The consensus of opinion is that evolution has occurred by a succession of small variations from the average, which conferred a slight but eventually important advantage in relation to the trend of environmental change. It is the existence of this galaxy of hereditary traits, varying only slightly from the accepted normal, that has conferred adaptability upon the human race. The recurrence of a small but steady incidence of harmful mutations is the price that has to be paid for this asset.

The Genetic Effects of Radiation: Basic Principles

119. There is as yet little direct information about the genetic effects of ionizing radiations on man and, for reasons which we examine later, the few observations that have so far been made present many difficulties of interpretation. We have therefore to rely on information obtained from experiments on other organisms. The experimental evidence is itself incomplete and largely derived from observations on forms of life other than mammals, but a general picture is beginning to emerge which appears to be consistent for the organisms which it has been practicable to study. The question arises, however, to what extent it is justifiable to draw inferences concerning man from the reactions of remote organisms observed under the artificial conditions of laboratory experiment. Since the genetic mechanism in man is the same as that in other animal and plant species, and since the animals and plants that have been studied all show the same type of genetic response to ionizing radiations, it would be unreasonable to suppose that the response in man will do other than follow the same general pattern. On the other hand, we do not think that conclusions derived solely from observations on other organisms offer a secure basis for quantitative estimates concerning man and, except where we have explicitly stated the contrary, we have not used them for this purpose.

Effects of radiation on germ cells

120. Ionizing radiation will have genetic consequences only in so far as it affects any of the germ cells or the cells ancestral to them in the reproductive organs. It may then have one of three results: the affected cells may die, their chromosomes may be broken, or the genes may be caused to mutate.

121. Death of a germ cell, or indeed of any cell ancestral to it, can have no genetic consequence, because this very death will terminate the lineage of cells to which it belongs.

Chromosome structural change

122. Chromosome breakage may also lead to death of the cell lineage. Broken chromosomes may fail to reunite or they may join up to give new forms of chromosomes which are incapable of passing through the process of cell division in the normal way; either of these circumstances leads to

subsequent death of the cell lineage. If the damage occurs in an immature germ cell in the sex gland, the cell lineage will usually die before mature germ cells are formed, and there will be no genetic consequences. If it occurs in a mature germ cell which later participates in fertilisation, the ensuing embryo will usually die early in gestation, and the ultimate genetic effects will be minimal.

123. Chromosome breakage may, however, have a different outcome if the fragments reunite in new patterns which are capable of passing through cell division. The resulting kinds of structurally changed chromosomes may be transmitted to apparently normal offspring, and at least one type of change will manifest itself by the occurrence of repeated abortions or malformations among the descendants of the irradiated individual. Experiments on mammals indicate that this inherited effect will appear only if conception takes place within a few months of irradiation.

124. Such structural changes of the chromosomes are induced especially by large single doses of radiation, for example heavy doses of X-rays or the prompt radiation from atomic bombs. They are induced only rarely by long-continued exposure to low-intensity X- or gamma radiation, although relatively small doses of neutrons or alpha particles are more effective in bringing them about.

125. Although they may cause partial sterility or abortion in their carriers, major structural changes of the chromosomes do not as a rule bring about other kinds of abnormality in individuals bearing them. For this reason, and also because of their low rates of spontaneous occurrence and induction by chronic irradiation, and of the probability of their having an adverse effect on fertility, chromosome structural changes are likely to be of comparatively little importance among the radiation hazards to man.

Induced gene mutation

126. The third and, from the genetical point of view, the most important effect of exposing germ cells to additional radiations is the induction of increased gene mutation. Since all germ cells from time immemorial have been continuously exposed to some radiation from natural sources, it would be surprising if exposure to additional radiation were found to induce any novel types of mutation. The results of experiment support this view; the types already known recur, but at an enhanced rate.

Proportionality of induced gene mutation to additional radiation

127. There is no known threshold for the induction of gene mutations by radiation: that is to say, any additional exposure, no matter how small, must be expected to raise the mutation rate, if only by a minute amount. Furthermore, to judge by our experience up to the present, it is probably true that the rise in the rate of mutations is directly proportional to the amount of additional exposure. This law is known to hold good, for such organisms as have been studied, when the radiation dose is fairly high. It is also known to hold good for the induction of one class of lethal genes in the fruit-fly, *Drosophila melanogaster*, by X-ray doses as low as 25 r. In this chapter of our report we are chiefly concerned with doses well below this level; but, for the present, there does not appear to be sufficient evidence to warrant the assumption that there is any real departure from this law even at the lowest doses, and proportionality has therefore been accepted as the basis of what follows.

Accumulated dose to germ cell lineage

128. Cells arise only from pre-existing cells. Mature germ cells are produced from a line of ancestral immature cells which have been present at every instant during the individual's life, from conception onwards. It will be remembered that mutated genes reproduce themselves as faithfully in a cell lineage as do the normal genes from which they arise. In consequence, the mutated genes arising throughout a germ cell lineage will be accumulated in the mature germ cell, and a given radiation dose will therefore have the same order of effect whether it is given over a short or a long period of time. In other words, long continued exposure to low-intensity radiation induces as much gene mutation as a single exposure to high-intensity radiation, provided that the total dose is the same. Experiments have shown that this probably remains true even when the dose is split into a series of small fractions, and no matter what interval elapses between the separate irradiations. Thus, in contrast to most other types of biological response to radiation, damage to the genetic material cannot be repaired and the effect from repeated exposures is cumulative.

Genetically effective dose to a population

129. This cumulative effect of radiation indicates that the genetic effects of exposure will depend on the ages of the individuals exposed as well as on the dose they receive. If, for example, all are past the reproductive age, the genetic effects will be nil; if they are younger, the possible number of offspring they may have is of importance. The age distribution of those exposed is therefore an important factor to take into account when estimating the consequences to future generations of additional radiation.

The Effects of Increased Mutation Rates on the Incidence of Disease in Human Populations

130. In approaching the problem of making some quantitative assessment of the genetic effects of radiation upon a human population, we have been very conscious of the inadequacy of the evidence in two essential respects. First, we do not know the dose of radiation required to double the mutation rate of any specified human gene; secondly, there is reason to suspect that the radiosensitivity of human genes may vary considerably, so that it could be very misleading to treat them as an approximately uniform group which would respond to any particular dose of radiation with a standard increase in mutation.

131. It is, however, possible to give a general idea of the effects of an increase in the mutation rate of particular human genes without raising the question of dose or degree of uniformity in sensitivity to radiation. We have therefore taken selected examples of diseases in which genetical factors are known to play an important part, and have attempted to assess the effects in a human population of doubling the spontaneous mutation rates of the genes concerned, without specifying the agent or agents causing this increased rate of mutation.

132. The role of heredity in the production of disease ranges from that of a predisposing to that of a preponderating cause. Thus, there is some evidence that heredity is a factor influencing susceptibility to tuberculosis; but this could be of no significance unless the individual were infected with tubercle bacilli. On the other hand, achondroplasia, a form of dwarfism, is probably determined entirely by genetic factors, in the sense that no known modification of the environment can prevent its appearance in those who possess the necessary gene.

133. In making our assessment we have confined our attention to those conditions which impose a significant handicap and which are determined, entirely or to an important extent, by hereditary factors. To put it another way, our object has been to give an assessment of the social load that would be imposed upon a population, like that of this country, by increasing mutation rates. We propose to consider two possible situations: first, when the mutation rate of every gene concerned is supposed to have been doubled in one generation only, thereafter reverting to its former level, and secondly when the rates having been doubled remain at that new level generation after generation.

THE EFFECTS OF DOUBLING MUTATION RATES ON DISEASES DUE TO A SINGLE GENE

134. For abnormal genes with effects which are masked in any way, either by normal alleles—as in recessive traits—or by the influence of environment, mutation has less immediate or less apparent consequences than for genes with effects which are directly manifest, as in dominant traits. Severely disabling dominant diseases reveal the results of recent mutation most readily. Sex-linked traits show a less rapid response. The effects of genes which produce recessive traits are masked until two genes come together in the homozygous state; hence, the results of their recent mutation will be less noticeable, although in the course of time their full effects will appear. Where a gene is common and mainly benign, but can occasionally cause disease, the results of its recent mutation will be scarcely detectable.

135. The effects which might be expected to result from an increase in mutation rates can most easily be calculated for diseases known to be caused by single genes (Appendix D). For this purpose we need to know what proportion of cases in a given generation is due to recurrent fresh mutation. The incidence of the particular disease in the population must be ascertained; so must its mode of inheritance (dominant, partially recessive, recessive or sex-linked), the degree to which it handicaps or favours the affected individuals—as shown by their length of life and reproductive capacity—and the modifying effect, if any, of environmental factors. This information is available for only a relatively few conditions and much more research will be required before we can feel reasonably confident in making estimates for groups of diseases. To illustrate the different types of effect, we have chosen three examples about which we have some fairly accurate information.

(*i*) *A dominant trait*

136. Achondroplasia (chondrodystrophia) is a dominant form of dwarfism. Although there are many clinical types, it will be assumed for the present purpose that the condition is due to a single gene with a manifestation which is independent of environmental factors. The incidence at birth, according to Danish estimates, is one in 9,400. Biological fitness is greatly reduced on account of high stillbirth rates and also, in adult life, on account of low fertility, especially of females. The chance that an affected individual will have offspring is estimated at only 1 in 5. The majority of cases are believed to arise through fresh mutation.

137. Doubling the mutation rate of the causal gene for one generation would produce an 80 per cent increase in the incidence of the condition in the first generation, that is the incidence at birth would rise to nearly one in 5,000. The excess would, however, rapidly disappear and within five or six generations the incidence would return to normal (Fig. 1a). If the

mutation rate were permanently doubled, the incidence would rise to a level close to double the present figure (i.e. 100 per cent increase) within three or four generations (Fig. 1b).

(ii) A sex-linked trait

138. The term haemophilia covers a group of sex-linked traits in which there is impairment of blood clotting. For the present purpose it will be assumed that all severe cases are caused by abnormal alleles at a single locus. The incidence is at least 1 in 12,000 of the male population at birth and the chances that an affected male will survive and have descendants is about one in eight. Females carrying the abnormal gene are healthy and have normal chances of reproduction. Doubling the mutation rate for one generation would produce a 29 per cent increase in incidence in the following generation, that is, the incidence would rise to about 1 in 9,300. In the next generation this level would be sustained but thereafter it would sink back moderately quickly towards the previous level (Fig. 1a). If the mutation rate were permanently doubled, the incidence would rise to 90 per cent above the previous level in about six generations, and thereafter slowly approach the point where the incidence was doubled (Fig. 1b).

(iii) A recessive trait

139. Phenylketonuria is an example of a deleterious recessive trait associated with severe mental deficiency. Its incidence in the population at birth is about 1 in 40,000 and, although the early mortality is not high, the chance that an affected person will have offspring is practically nil. A doubling of the mutation rate in one generation would cause an increase of one per cent in the incidence of the disease in the first generation. If allowance were made for the effects of inbreeding, a further small increase would be predicted sometime after the second generation and this would be followed by a very slow return to the previous level (Fig. 1a). The response to a permanent doubling of the mutation rate would be a slow rise by almost equal increments. It would take more than 50 generations of 30 years each to increase the incidence by 50 per cent, and many more to approach an increase of 100 per cent (Fig. 1b).

THE EFFECTS OF DOUBLING MUTATION RATES ON BROAD GROUPS OF DISEASES

140. The three examples given above illustrate the kind of result to be expected from doubling the mutation rates of genes representing each of the three classical types of genetical effect. A large number of dominant, sex-linked and recessive diseases are known; many of them are rarities but together they may account for a relatively large proportion of serious hereditary disability in the population. However, to give an idea of the extent of the problem of hereditary disability, and the total results of doubling the mutation rates of the genes which are responsible, common categories of illness must be considered. Our information, from the genetical point of view, is unfortunately not often precise and, in addition, the effects of genes are in many cases modified by environment. Mental diseases and mental deficiency, when taken together, account for nearly half the hospital beds provided in this country and are the most extensive inclusive category in which hereditary causes are known to be important. We shall first consider severe mental defect and then the two main types of mental illness.

(i) Severe mental defect

141. The incidence in the population of cases of severe mental deficiency which survive has been estimated to be about 1 in 500. It is higher than this at birth but subsequently reduced by the heavy mortality in early life. Beyond

this, there are grossly affected individuals, many with malformations of the nervous system, who are stillborn or who do not survive early infancy but who would have been mentally defective had they lived; the incidence of such cases is at least 1 in 200. The number of cases of severe defect at all ages surviving in England, Wales and Scotland may be nearly 100,000. The fact that not far from 30,000 hospital beds are provided for these cases indicates the extent of the medical care required.

142. In this broad category of disease, conditions with dominant inheritance include epiloia (sebaceous adenoma with tuberose sclerosis), several types of acrocephaly, hypertelorism and neurofibromatosis. In such diseases, many of the severely affected cases, say one half, can be attributed to recurrent fresh mutation. Doubling of all the mutation rates, for one generation, would have a large effect in the subsequent generation, and a permanent doubling of the mutation rates would soon permanently double the incidence. We may suppose that diseases such as these, collected together, form four per cent of all surviving cases of severe mental defect, as shown in Table 1. If all mutation rates were doubled, this would add 50 per cent to the numbers of these cases in the first generation, that is to say two new cases in every 100 in the whole category, an increase which would mean a thousand extra cases requiring medical care.

TABLE 1

Effect of doubling mutation rates of genes concerned with severe mental deficiency: cases per generation classified according to probable causation

Type of Diagnosis	Probable causation	Surviving cases of severe mental deficiency under present conditions (i)*	(ii)†	Increase in first generation if mutation rates are doubled (i)*	(ii)†
Acrocephaly ... ... Epiloia ... ... Neurofibromatosis ... *et cetera*	Dominant gene	4·0	2,000	2·00	1,000
Microphthalmos ... Gargoylism ... ... *et cetera*	Sex-linked gene	0·5	250	0·15	75
Amaurotic idiocy ... Cerebral diplegia ... Phenylketonuria ... 'True' microcephaly ... *et cetera*	Recessive gene ...	40·0	20,000	0·40	200
Mongolism	Environmental influence plus common genetical susceptibility	12·5	6,250	?+	?+
Others	Miscellaneous, including birth injury and infection	43·0	21,500	?+	?+
All	—	100·0	50,000	3·0	1,500 (approximate figures)

* (i) percentages based upon all cases in the category.

† (ii) numbers which would occur in a generation of 20 million births.

143. A few rare diseases causing severe mental defect are known to be due to sex-linked genes, for example one type of microphthalmos and one type of gargoylism (Hurler's syndrome). The contribution of this group to the total number of defectives is small and can hardly exceed half of one per cent of severe cases. Nevertheless, for the reason given above, diseases of this kind must be due to genes with significant mutation rates: if these rates were doubled in one generation, the incidence at birth of the diseases would be increased by nearly one-third, as in haemophilia. After a doubling of the mutation rates in one generation, there would be an increase of 0·15 per cent in the total number of cases of severe mental defect, or 75 extra cases requiring medical care.

144. Other important known genetical causes of mental defect are recessive conditions, such as the two kinds of amaurotic idiocy, phenylketonuria, cerebral diplegia, and 'true' microcephaly. Known conditions caused in this manner account for 20 per cent of low grade mental defect and the same type of causation may easily account for twice as much as this. The case frequency of these traits individually is low, that is about one in 40,000 in the population at birth; about 20 conditions of this type are already known and perhaps another 20 may exist undetected. Since these diseases are all very deleterious, so that those affected scarcely ever have offspring, it is generally accepted that the genes causing them arise continually by spontaneous mutation. As previously explained, the reason for this assumption is that the incidence in the population can only be maintained if loss of genes through failure of reproduction is balanced by an equivalent appearance of new mutations. From this consideration the mutation rates can be estimated for these recessive traits but the method is indirect and the results are imprecise; they are likely to be too high. A doubling of mutation rates in one generation would cause a one per cent increase in the incidence of each lethal recessive trait the original incidence of which is one in 40,000. If 40 per cent of severe mental deficency were determined in this manner, doubling mutation rates would cause an increase of 0·4 per cent in the whole category or 200 extra cases requiring medical care.

145. The problem of mongolism, a disease responsible for between 10 and 15 per cent of all cases of severe mental defect living in the population requires separate consideration. There is strong evidence of a genetical element in the causation but maternal age is also a very significant factor. The hereditary predisposition must be very common and only harmful in exceptional circumstances. Although a slight increase in incidence might be expected as a result of doubling mutation rates, the nature of the predisposition is so imperfectly understood at the present time that it does not seem useful to make a numerical estimate for this condition.

146. As shown in Table 1, 43 per cent of the cases are not yet accounted for. Among these, there must be a large group in which injury or infection is the main cause, perhaps 15 per cent of all cases of severe mental defect. A still larger number are of quite unknown origin, although genetical factors may have some influence. Furthermore, there may be a residual proportion of cases due to relatively common genes, acting either singly or in combination with one another, on which the effect of increased mutation could be appreciable. It is impossible to make quantitative predictions about mutation for this group with unknown causation but the number of cases ordinarily caused by fresh mutation must be very small.

147. The conclusion is that, after doubling the mutation rates, an overall increase of three per cent in the category of low grade mental deficiency in one generation is possible; in a generation of 20 million births the known

surviving cases would number 50,000 and an increase of three per cent would mean 1,500 additional cases requiring care. If the mutation rate remained permanently doubled, the incidence in the population would, on the most pessimistic assumptions, eventually, after very many generations, double also and twice as much medical care would accordingly be needed.

(*ii*) *Mental illness*

148. Current theories concerning the genetical factors underlying mental illness imply that a small but substantial proportion of cases must owe their origin to the recurrence of mutations. This is almost certainly true for Huntington's chorea, a rare dominant disease. For the common disease groups, schizophrenia and manic-depressive reaction, the situation is less clear. According to figures for 1954, there were approximately 63,000 cases of schizophrenia and 31,000 cases of manic-depressive reaction under hospital care in England, Scotland and Wales. Since these diseases account for about half of all mental illness, it may be worthwhile to attempt a rough estimate of the effects of changing mutation rates upon their incidence.

149. Theoretically, any genes responsible for conditions, like mental illness, which lower biological fitness to a marked degree would have been eliminated from the population, or would have become very rare, unless they had been continually replaced by fresh mutation. However, there are uncertainties about the relevant facts concerning the genetics of schizophrenia and manic-depressive reaction. First, the incidence of these diseases in the population is not accurately recorded; secondly, the biological fitness of predisposed and even of affected individuals has not been fully investigated; thirdly, the nature of the genetical contribution is known only by surmise; and, fourthly, nothing definite is known about possible compensating mechanisms which might, if they existed, make unnecessary the assumption of gene replacement by spontaneous mutation.

150. Calculation, on the basis of elementary and simplified assumptions about gene action, leads to the conclusion that doubling the mutation rate might have the effect of raising the incidence of schizophrenia by a factor of one per cent and of manic-depressive reaction by a factor of 1·4 per cent in the first generation. It is not possible to estimate the number of extra hospital beds which this proportional increase in frequency of genetical predisposition would imply. We can, however, obtain an idea of the expected number of extra chronically incapacitated patients from the calculations set out in Appendix E. The total number of such cases which would appear among the first generation of 20 million births after doubling mutation rates would be 200 schizophrenics and 200 manic depressives. The number of extra patients needing psychiatric care at one or other time during their lives, on account of these genetical predispositions, would be from 5 to 10 times as great. A permanent doubling of mutation rates would have in each succeeding generation an effect similar to that in the first generation. Thus, over a very long period of time, the number of cases would slowly increase until the limiting value of twice the initial number was approached.

(*iii*) *Blindness*

151. A frequent cause of severe disability is blindness. The extent of the morbidity is shown by the fact that every year, in England and Wales, 12,500 new cases of blindness are registered. These include cases of developmental abnormality, tumours, metabolic diseases and the results of injury and infection. The genetical background is extremely varied but at least half of the hereditary cases can be attributed to single genes, often recessive like those causing retinal degeneration, though a few are dominant like that for

retinoblastoma; some are known to be sex-linked. High myopia is believed to have a complex genetical background. The important cases from the present point of view are those with onset in early life and about three-quarters of all such cases of blindness are thought to be hereditary. About 300 children between the ages of 0 and 15 years are registered as blind annually. Severe cases in the causation of which mutation is likely to play an important part will mostly be in this group which includes aniridia, microphthalmos and retinoblastoma. The mutation rates for these dominant diseases are listed in Appendix C. Assuming that these figures apply to England, Wales and Scotland, we can estimate that, in one generation of 20,000,000 births, there would be 80 cases of aniridia, 80 cases of microphthalmos and (using the mean of three estimates) 560 cases of retinoblastoma due to spontaneous mutation in ordinary circumstances. These numbers would be almost doubled if the mutation rates were doubled for one generation. If the mutation rates were permanently doubled, this increase would be continued until the total incidence of these diseases was doubled, as was calculated for achondroplasia.

152. Numerous cases of blindness due to recessive conditions are known, and some have sex-linked inheritance. Figures for the incidence of these traits are not well enough established for the effects of doubling mutation rates to be estimated.

(iv) *Neonatal deaths, stillbirths and congenital malformations*

153. An increase in mutation rates would be expected to have an effect upon the abortion, stillbirth and neonatal death rates and upon the incidence of congenital malformations. These deaths and malformations are known to be caused in large part by the environment of the unborn child, which may be affected by illnesses and other conditions in the mother. Many may be due to single recessive genes, some to chromosome abnormalities and others are known to be caused by immunological incompatibility between mother and foetus. For these reasons we have not found it possible to make detailed calculations of the kind used above for other conditions, but it is certain that the total effects of doubling mutation rates in one generation would be slight. Observations on these foetal conditions in actual circumstances where the mutation rates might have been increased have been made on human populations and are discussed below in paragraphs 162 to 170.

THE OVERALL LOAD OF ILLNESS IMPOSED BY DOUBLING ALL MUTATION RATES

154. We have expressed the opinion that, from the standpoint of the social load imposed, mental diseases constitute the most important single category of disease which is determined to a marked degree by heredity and which is serious, in the sense both of being highly harmful to the individual and of making heavy demands on medical resources. We are aware that this is only an opinion and that others may have different views. We believe, however, that it will be conceded by all that the mental diseases contribute a very substantial proportion of the total number of those suffering from serious hereditary disorders. It seems reasonable, therefore, to suggest that the total increase in the social load due to serious hereditary illness of all kinds, which would follow doubling all mutation rates, would be unlikely to exceed more than a few times the estimates we have given for mental defect and mental illness combined.

155. Hereditary diseases are sometimes thought of as incurable, and it is true that present knowledge provides no grounds for believing that cures will

be found for some of the grosser forms. With the advance of medical science, however, it has become possible to alleviate many hereditary conditions or even to maintain the affected patients in good health. A classical example is diabetes mellitus, into the causation of which a hereditary factor enters in many cases. Before the discovery of insulin, the majority of diabetics were destined for invalidism or premature death. Now with its aid they live essentially normal lives. With further advances of medical knowledge, it may be expected that an increasing number of hereditary conditions will be brought into this category, and thus the load of suffering from illness of this kind be reduced. It should be realised, however, that the preservation of those afflicted by hereditary conditions will increase their chances of having children and so lead to an increased prevalence of the condition in the population and with it an increased need for medical services.

156. From the point of view of the long-term effects on the population, it must be remembered that, even though most of the new recessive alleles produced by an increase of mutation rates will not meet a like partner in the first generation after they are produced, and will therefore remain concealed, they will still exist in the population. They will in fact persist until, at some later time, two carriers of like genes happen to mate. The recessive effects will then become manifest in some of the children of such matings. If such genes are harmful, these affected children will produce fewer offspring than the normal, so that there will be a reduced chance that the genes will be passed on to later generations. In this way mutated genes can eventually die out. The extinction of the gene will have been brought about, however, only by the failure of some affected individual or individuals to reproduce at the normal rate, a circumstance which may sometimes be merely unfortunate but in other cases may be the expression of a hereditary defect which causes great suffering. Thus, if the mutation rate is increased, and a crop of newly mutated recessive genes produced, they will continue to cause harmful effects for many generations.

The Effects of Increased Mutation Rates on Hereditary Traits showing Continuous Variation about the Normal

157. Although in any human population we can find individuals who are physically, biochemically or mentally abnormal in a relatively gross way and whose abnormality can be traced to single gene differences, most of the variation between human beings is not in fact of this kind. Even in that greater part of the population which we should describe as normal, no two individuals are alike: they vary by imperceptible gradations over a wide range in respect of many characters such as physique, general well-being, life-span, intelligence and so on. Some of the variation is hereditary but some is due to differences in environment—in the circumstances under which the individual lives and has grown up. The hereditary portion of this variation is believed to be due to the combined action of many genes which supplement one another in producing their effects. These genes cannot be distinguished one from another, and their effects have therefore to be measured in a way differing from that used where a gene has consequences sufficiently drastic for it to be followed as a separate entity. The importance of heredity in such cases is expressed by estimating the proportion of the variation which is traceable to gene effects. The properties of the system of genes are inferred from observations on the amount of this variation which is shared by relatives and on the change in the proportion from generation to generation. In particular, the effect of mutation will be measured by the increment it adds to the variation in each generation.

158. One difficulty should be observed at the outset. The success of this method of approach depends on the ability to measure separately the proportions of the variation attributable to the combined effects of the genes, and the proportion attributable to environmental factors external to the individual. Even in animals and plants, under the conditions of controlled experiment, this is not always easy. In man, whose parents give him not only his genes but also the home and environment in which his early and most formative years are passed, the separation of hereditary and environmental effects is always extremely difficult. Observations on, for example, children brought up by foster parents are of some assistance; but, even so, the conclusions at which we have been able to arrive must be regarded as rough estimates and treated with due caution.

159. Genetic theory leads us to expect that, since mutation brings new gene differences into the population, the basic effect of an increase in the mutation rate will be to increase the variation shown by these characters, that is to raise the numbers of the more extreme types at the expense of the more central, average individuals. Very little information is available, however, even from experimental animals and plants, about the magnitude of the effect to be expected. Such few observations as we have (Appendix F) suggest that in any generation the variation due to new mutation is but a small fraction of the heritable variation observable, and, of course, a still smaller fraction of the total variation, which includes that due to the environment. Indeed, the available data would lead us to expect that hundreds of generations of mutation would be needed to build up the variation which is seen in a human population. A doubling of the mutation rate for a few generations would therefore be expected to have only the most trivial effect on the variation in such characters, and even a persisting doubling of the mutation rate would take very many generations to approach its full effect, which at most would be to double the variation.

The distribution of intelligence

160. The effect on the distribution of intelligence—or, more accurately, of the score in intelligence tests—of an increase in the hereditary variation, such as would be expected to result from a raised mutation rate, is considered in Appendix G. Extensive studies have been made of the intelligence score and something is known about its distribution in the population and the extent to which it is inherited. Increase in the variation, that is in the spread of the distribution, will lead to an increase in the numbers both with markedly low and markedly high scores. Furthermore, the more extreme the class under consideration, the greater the increase in its numbers relative to the overall change in the variation. Thus, from the table in Appendix G, it will be seen that a doubling of the heritable variation could lead in the long run to nearly a tripling of the numbers falling short of an intelligence score of 70 and conventionally regarded as requiring special schooling. On the assumption that the average score did not fall, a corresponding increase would be expected in those with the high scores of over 130.

161. The increase in the two extremes of the distribution may, however, not be symmetrical. Evidence from experimental organisms shows that, where a character has been subjected in the past to much selection in a particular direction, new variation is likely to produce a disproportionately large increase of the more extreme types in the direction opposite to that towards which selection has been pushing the character. This would still be true when the variation is being increased by irradiation. It seems probable, in the light of man's evolutionary history, that he has been subjected to fairly

intense natural selection for increased intelligence. It might therefore be expected that an increase in the variation, resulting from a raised mutation rate, while leading to some increase in the fraction of those who are highly intelligent, would lead to a greater—perhaps much greater—increase in the other extreme fraction with low intelligence. In addition to the calculation which assumes that the average intelligence score remains constant and so assumes symmetrical increases at the two ends of the distribution, Appendix G includes a calculation which assumes an asymmetrical effect, the overall average of the population falling but the proportion of children of grammar school ability remaining constant. The disproportion in the increase of the low end of the distribution is of course increased, a doubling of the variation raising the proportion with a score of less than 70, perhaps by as much as four or five times. It should be remembered, however, that these calculations apply to the situation when the increase in variation has reached its full extent. We have already seen that such data as are available suggest that a permanent increase in the mutation rate would take hundreds of generations to produce its full effects on hereditary variation.

Observations on Populations Exposed to Radiation

162. An alternative approach to the problem before us, and one which in addition might provide direct evidence of the relation between the dose of radiation and increased incidence of hereditary traits in man, is to observe the effects on human populations which have been exposed to ionizing radiations. Three such studies have been carried out, two on American radiologists and the other on the Japanese populations who were in Hiroshima and Nagasaki at the time of the atomic bomb explosions. For various reasons, the evidence from each is inconclusive, even that from the extensive study by the Atomic Bomb Casualty Commission in Japan.

Possible indicators of change in mutation rates

163. Among the possible indicators of a change in the mutation rate are changes in the sex ratio at birth, the congenital malformation rate, the stillbirth rate, the neonatal death rate, the weight at birth, the weight at nine months, and measurements of the head and body. Changes in the sex ratio may be used as an indicator of genetic damage. The inheritance of abnormal genes in the sex chromosomes has been considered in relation to haemophilia. Experimental observations have shown that abnormal genes which kill the infant long before birth can be carried on the sex chromosomes and there is reason to believe that this may be true in man. Such genes will necessarily disturb the sex ratio at birth; mothers with such mutations will have too few sons, and, in rare cases, fathers too few daughters.

164. It is known, from both human and experimental evidence, that genes can produce abnormalities which are evident at birth. Estimates of the congenital abnormality rate vary with different observers from just over one per cent to about six per cent, owing to lack of agreement on what shall be reckoned an abnormality as well as to real differences in populations with respect both to their environments and to the frequencies of the causal genes. Further, genes are not the only cause of such abnormal conditions. Both clinical and experimental evidence suggests that maternal ill health, particularly infectious disease and malnutrition during pregnancy, can produce them. There is no definite information as to what proportion of cases of malformation should be attributed to the effects of single genes; nor are the forms of inheritance understood.

165. The stillbirth and neonatal death rates are also influenced by a variety of factors. The evidence that abnormal genes can play a part is based

partly upon experimental genetics and partly upon investigations of family histories. On the evidence available at the present time, it is difficult to estimate the extent of the part played by genetical causes.

Genetic studies on radiologists

166. The evidence provided by the studies of congenital abnormalities in the offspring of American radiologists is inconclusive for two reasons. First, no measurements were made of the radiation doses which were received by the radiologists in the course of their work and it is virtually impossible to deduce these in retrospect. Secondly, the data were obtained by postal questionnaire, to which only three-quarters of the radiologists replied and little over half the other specialists who were used as a control group. Whether those who chose to answer were representative of the total is open to question. As the magnitude of the effects observed was small (slight rises in the incidence of twinning, foetal death and congenital malformation), one cannot exclude the possibility that the increases were due to statistical bias in the data rather than to the radiation exposure, or alternatively that statistical bias in the other direction may have partly concealed a somewhat larger increase than was observed.

Studies on Japanese populations

167. The Atomic Bomb Casualty Commission's genetic study was much more extensive. An attempt was made to assess the prompt radiation dose received by each individual; and in each city those remote from the burst constituted a control population with which to compare those close to it. More than 80,000 subsequent pregnancies were followed, and a third of the children were re-examined at nine months of age.

168. The final report on the genetic programme of the Atomic Bomb Casualty Commission has not yet been published; but through the courtesy of the United States authorities, and especially of Dr. James V. Neel and Dr. William J. Schull, we received copies of the draft and are permitted to refer to it. The data present many difficulties of interpretation for several reasons. First, the radiation dose was not known with any accuracy. Second, the parents with different degrees of exposure were not entirely comparable in various characteristics, such as maternal age at birth of the child, to which the congenital malformation rate is related; for this reason, even if there were no effect due to exposure, the children of the highly exposed parents would be expected to differ in their congenital malformation rate from those of the slightly exposed. Complex statistical procedures are necessary to allow for this. Even more open to error is the comparison between the children of exposed parents and those of parents who were entirely unexposed. The latter group of parents included immigrants from other cities or from rural areas after the time of the bombing, and some who were away from home at the time, and the effect of these factors on, say, the congenital malformation rate is quite unknown. Thirdly, the number of people who survived high exposures was not large and therefore there were comparatively few births in this group; estimates of the incidence of congenital malformations and other abnormalities are consequently of low statistical precision, being open to relatively large disturbances through the operation of chance. Fourthly, only small effects would be expected in any given generation, even if the mutation rate had been raised many times.

169. Any opinion on a report which is still only in draft must be regarded as provisional. In our view, however, the data suggest an effect of the bomb radiations on genetic factors in prenatal survival, as shown by the sex-ratio at birth. The evidence for this effect is not highly significant statistically

and any change which was induced in the sex-ratio is unlikely to have exceeded 2 per cent per 100 r exposure of one parent. This appears to be the only positive conclusion that might perhaps be drawn but it is possible, for several of the measurements, to set upper limits to the changes that might have occurred without being detected. From the nature of the evidence a possible doubling, but not more than doubling, of the congenital malformation rate, or a 50 per cent rise in the stillbirth rate, following exposure of one parent to 200 r, might have escaped detection.

170. Although it was possible to set an upper limit to the increase in sex-ratio, congenital malformation rate and stillbirth rate, we were unable to do so for the increase in mutation rates of the genes responsible. For this purpose it would first be necessary to know what proportion of prenatal death or malformation is in ordinary circumstances due to newly mutated genes and what proportion to genes already present in the population. We cannot, therefore, derive from the Atomic Bomb Casualty Commission's data any estimate of the mutation-rate-doubling radiation dose for man.

The Radiation 'Doubling Dose' for Human Mutation Rates

171. At this stage it becomes necessary for us to attempt to give a quantitative estimate of the magnitude of the effect of any given dose of radiation on the mutation rate in human populations. This is an extremely difficult task, since not only have we as yet too little precise information on which to base an accurate estimate, but also it is by no means simple to know in what terms the effect should best be measured.

172. We have seen that all genes mutate spontaneously. The spontaneous mutation rate (s) of any particular gene can be considered to be made up of two parts; some of its mutations (x) will be provoked by the naturally occurring radiation, while others (y) will be due to other influences, so that $s = x + y$. It would be easy to find a theoretically adequate measure of the effect of increased radiation on mutation, if all mutations were caused by radiation of some kind, y would then be zero; and, since we have seen (paragraph 127) that radiation-induced mutations increase in simple proportion to the amount of radiation, it follows that, if the amount of radiation were doubled, the mutation rate would be doubled also, and so on. We could express the effect of increased radiation in terms of the 'doubling dose', that is the quantity of radiation required to double the spontaneous mutation rate. It is clear that the doubling dose under these circumstances would be equal to the naturally occurring radiation.

173. However, as we shall see later (paragraph 178), there is good evidence that in the few well-studied animals spontaneous mutations are not due solely to radiation, and therefore we cannot safely assume that y is zero. The situation would remain fairly simple, provided x and y were always in the same proportion, so that we could assume that a certain constant fraction of the spontaneous mutations of each gene is caused by natural radiation; but this also seems unlikely to be the case. Older parents have accumulated higher doses of radiation than younger parents; if all genes were equally sensitive to radiation, the frequency of all new mutations should then show the same increase in the children of older fathers as in the children of older mothers. It is found, however, that for some human genes, but not for others, the increase is more marked in children of old fathers than in those of old mothers. This fact suggests that the genes which exhibit this relationship to paternal age differ from other genes in that their mutation is dependent in an important way on something other than radiation, perhaps on the number

of cell divisions since conception, which is much greater for sperm than for eggs. There is also some evidence from experiments on flies and other organisms, in which high doses of radiation were employed, that certain genes are more radiation-sensitive than others. In view of these facts, it is only safe to assume that the same may be true of human genes, and that for each gene the spontaneous mutation rate is built up of both an x and a y fraction, which do not always bear the same proportionate relation to each other.

174. If this is so, an amount of extra radiation which will double the mutation rate of the most radiation-sensitive genes will have a much smaller effect on the more radiation-tolerant ones. It is then impossible to give any one figure which will measure the effect of radiation on the whole set of genes. However, in practice we still know so little about human mutation rates that we can, provisionally, make some simplification of the theoretical considerations. We can attempt to assess the effects of increased radiation in terms of that dose of radiation which will double the spontaneous mutation rate of an adequate and representative sample of the most sensitive genes. This would be a minimum estimate of the doubling dose. By 'adequate and representative' we mean that we must consider a sufficient number of the more sensitive genes to get examples of all the different kinds of genetic effects. Fortunately there is no reason to doubt that, if one considered a fairly large number of the most radiation-sensitive genes, they would contain examples of genes with all possible kinds of effect. We shall assume that this is indeed so, and, further, that there are sufficient genes with roughly the same degree of radiation-sensitivity for us to employ the concept of a representative doubling dose of radiation of the kind which we have been discussing.

175. The attempt to estimate a figure for the minimum representative doubling dose in man is beset with many difficulties. We have as yet no useful direct evidence. The only data which might provide information about actual increases in human mutation following irradiation are those from the investigations of the results of the atomic bombs in Japan, and those on the offspring of radiologists, and, as we have already seen (paragraphs 162-170), in neither is the material sufficient to lead to any firm conclusions. At the present time, therefore, we are driven to making indirect estimates.

176. Perhaps the most firmly based line of argument towards an indirect estimate is one which leads us to an assessment of a minimum figure above which the doubling dose must almost certainly lie. Let us suppose that all human spontaneous mutations are radiation-induced; then, provided the mutation rate increases in direct proportion to the radiation, the doubling dose would be the same as the quantity of natural radiation received. The only way of escape from this argument would be by the supposition that for human genes the mutation rate is not directly proportional to the radiation, but that they are comparatively insensitive to small doses up to the level of natural radiation, and relatively much more sensitive to doses slightly greater than this. There is no evidence in any other animal for such an effect, but a few experiments in plants, the results of which are not entirely consistent, have suggested an effect of this kind, though only a slight one. It therefore seems safe to argue that, even under the most pessimistic assumption that all human spontaneous mutations are induced by radiation, the doubling dose could not be less than the normal amount of natural radiation. It will be seen, in the chapter on exposure levels, that in this country, over a period of 30 years this amounts to about 3 r to the reproductive organs. We may therefore take this figure as the lower limit of our estimate.

177. The next step is to try to determine whether the actual value of the doubling dose is quite near this limit or considerably above it. There are several ways in which we can proceed. We may first ask whether the Japanese data are compatible with a doubling dose as low as 3 r, or whether, if the value were as low as that, one would have to anticipate rather striking effects in place of the almost complete absence of definitely significant results which was actually observed. Calculations show that, if some more or less plausible assumptions are made, the absence of definitely recognisable effects in the Japanese data does not contradict a doubling dose as low as 3 r, although it is of course more easily accounted for if the real doubling dose is considerably higher.

178. Our lower limit for the doubling dose was based on the supposition that all spontaneous human mutations are caused by radiation. If natural radiation accounts for something less than 100 per cent of spontaneous mutations, then this lower limit would be raised accordingly. In experimental animals, one can determine what fraction of spontaneous mutation is due to radiation by measuring the effects of several different large radiation doses and extrapolating the results to the naturally occurring dose. Even among experimental animals, it is only for fruit flies that we yet have sufficient information to do this with much confidence. It turns out in this case that natural radiation accounts for only about one ten-thousandth (0·0001) of their spontaneous mutations. In trying to extend this result to man, we have to take into account two considerations. The first is that the longer the time elapsing between the conception of an individual and his reproducing, the greater the dose of radiation he will accumulate. The second is that, if the genes are equally radiation-sensitive in two species, the fraction of the spontaneous mutation induced by natural radiation will be smaller if the spontaneous rate is large than it would be were the spontaneous rate small. If one compares the lengths of the pre-reproductive periods of man and flies one finds that man has time to accumulate about 1,000 times as much radiation as the fly. We are much less certain about the comparison of their spontaneous mutation rates, since figures for man are not available for many loci (Appendix C). However, estimates have been made that the human mutation rate is probably about five times as great as that in flies. We should then find that the fraction of the human spontaneous rate due to radiation can be estimated at 1,000/5 times the fraction which holds for flies. i.e 200 × 0·0001, or about 2 per cent.

179. The argument given above is based on the hypothesis that the sensitivity of human genes to radiation, that is the mutation rate induced per roentgen, is the same as it is in flies. As has been repeatedly pointed out, we have no definite evidence about the radiation-sensitivity of human genes, by which this assumption could be checked. The mouse is the only mammal for which we have any evidence on the radiation-sensitivity of genes. The induced mutation rates for a small number of genes have been roughly measured for this species. The experiments suggest that its genes are about ten times as sensitive as fly genes; but it should be noted that this figure depends very largely on only one of the seven genes tested. However, in order to be cautious we may make the hypothesis that mouse genes are ten times as sensitive as fly genes, and that human genes are similar to mouse genes. According to this hypothesis, we must increase our estimate of the fraction of human spontaneous mutation rate due to radiation by ten times, from 2 per cent to 20 per cent.

180. According as we suppose the radiation-induced fraction of the spontaneous mutation rate of man to be 20 per cent or 2 per cent, we arrive

at estimates for the doubling dose that are five or fifty times the naturally occurring radiation, that is 15 r or 150 r. It must be pointed out, however, that the calculations which have just been given have involved a number of quantities which are still only imperfectly known; for instance, the spontaneous mutation rates of flies, mice and particularly men. One cannot therefore, on this basis, absolutely exclude the possibility that the doubling dose may actually lie somewhat below 15 r.

181. Various other theoretical methods have been suggested for utilising the data about experimental animals to calculate a doubling dose for man. They all lead to values within the same rather wide range as we have just reached. Moreover, they all involve even more conjecture about quantities on which we have little precise information, such as the comparative numbers of gene loci in man and other animals. We shall not attempt to summarise them here.

182. There is another rather different type of approach to the problem; that is, to compare the values of the minimum representative doubling dose in the animals and plants for which we have the most reliable data (Appendix H). They mostly run from about 25 r upwards, many of them being between 25 and 60 r. Only a few types of organisms have yet been studied in detail, but taken as it stands this evidence would suggest that all doubling doses lie in about the same range, and it is therefore possible that man's may do so too. It is unfortunate, though easily understandable, that none of the fully investigated organisms has a lifetime comparable in length to that of man, and this suggests the necessity of caution in applying the results to man. But one might expect, *a priori*, that evolutionary processes would have acted to reduce the radiation sensitivity of the genes of organisms with long pre-reproductive periods, so that they would have higher doubling doses. Thus, this line of approach would lead us to expect the human doubling dose to lie above 25 r.

183. The discussion in the last few paragraphs has been given at some length in order to bring out the great uncertainty of our present knowledge of the doubling dose for most human genes. Mustering all the arguments at our disposal, we can only come to the conclusion that it almost certainly lies above 3 r, but that it may be as much as 150 r or even more. Any statement which goes beyond this can only be phrased in terms of probabilities, and depends on a judgment made by balancing all the different lines of argument against one another. In this tentative fashion, we should advance the view that there is little likelihood that the representative value lies between 3 r and 15 r; and that, although we cannot exclude the possibility that for some human genes the doubling dose may be less than 30 r and for others more than 80 r, the best estimate which we can make, in the light of present knowledge, is that the representative value lies between 30 r and 80 r.

184. It remains to consider what dangers would arise if we have, for lack of adequate information, materially over-estimated the value of the doubling dose for human genes. Even if we suppose that it is actually as low as the minimum that we can reasonably entertain, namely 15 r, it is extremely improbable that in times of peace the whole population, or a large fraction of it, will receive an additional dose of this magnitude from industrial or other sources. We need not therefore anticipate any general danger. There may, however, be small groups of people, for instance those employed in certain industrial processes or receiving medical treatment involving X-rays, who may be exposed to doses near the representative doubling dose. Have they grounds for fearing any disastrous effects on their descendants? In the first place, it is obvious that if, for reasons of age or other considerations, they do

not reproduce after the period of exposure, no genetic effects at all will eventuate. If they do reproduce, there are two aspects to be considered: the effect on their immediate offspring and the effect on their later descendants.

185. We shall consider first the immediate descendants. It has been calculated on theoretical grounds that at the present time, without any additional radiation, approximately one human germ cell in ten (10 per cent) carries a new mutation. The great majority of these are recessive, and only very rarely have an effect on immediate offspring. Probably not more than one in a hundred is a dominant, the action of which will be seen in the next generation. Thus, a doubling of the mutation rate might lead to an increase of one in a thousand (0·1 per cent) in the numbers of harmfully affected children in the next generation. This must be compared with the present chance that the children born in a family will be congenitally defective. At present, about four per cent of all babies are stillborn or die shortly after birth, while another two per cent survive but are malformed; and in addition a considerable number in later years develop diseases or abnormalities in which hereditary constitution is a preponderating cause. Thus a doubling of the mutation rate in one parent would only add to the chance of producing a defective child an additional 0·1 per cent. above the present level of about seven to eight per cent.

186. A more realistic estimate of individual genetical risk can be obtained from the figures given in paragraphs 141 to 150. For example, the ordinary risk that any pair of parents will produce an imbecile or an idiot—that is a case of severe mental defect—which survives, is about one in 500. The increased proportional risk for parents in both of whom mutation rates have been doubled is three per cent; this means that the risk of their having a child with severe mental defect which survives is one in 485. If only one parent is affected, the risk would be increased by a factor of 1·5 per cent, so that the chance would then be about one in 493. Similarly, the risk of producing psychotic offspring might be increased by a factor of one per cent if mutation rates were doubled in both parents and by half this amount if only one was affected. The likelihood of miscarriage, stillbirth, or foetal malformation would probably be even less increased; compared with the changes in incidence which occur, for example, at different maternal ages or between the first and later births, these alterations would be inappreciable. The risks of occurrence of specific dominant or sex-linked traits, such as those listed in the table of human mutation rates (Appendix C), would indeed be proportionately much more markedly affected; but, because of their rarity, the risks of these abnormalities are ordinarily considered negligible for the individual and, even after being nearly doubled, they would remain so.

187. In ordinary circumstances, if a parent carries any given allele, the chance that one of his offspring receives it is one in two; a grandchild has one chance in four of receiving it and a great-grandchild has one chance in eight. The same rule applies to an allele which has arisen by fresh mutation in the parent. Thus it follows that the extra risk of disability, which applies to the children of an individual who has been exposed to doses of radiation causing mutation, will be halved in each subsequent generation of his offspring, provided that the level of mutation rate in the rest of the population has not also been raised. Moreover, it must be remembered that under natural conditions every human being already carries a certain number of harmful recessive genes, the results of spontaneous mutation in the past. There is therefore no reason why an individual in whom the mutation rate has been doubled, or increased by some similar figure, need fear that he runs an appreciable risk of founding a 'bad line' of descendants.

188. One may conclude that, if a relatively small group of prospective parents receives a doubling dose of radiation, no noticeable effects will be produced either on their immediate offspring or upon their descendants. For levels of radiation up to the doubling dose, and even some way beyond, the genetic effects of radiation are only appreciable when reckoned over the population as a whole and need cause no alarm to the individual on his own account.

CHAPTER V

EXISTING AND FORESEEABLE LEVELS OF EXPOSURE TO RADIATION

Introduction

189. Throughout the whole of his evolutionary history man, like all living organisms, has been exposed to small but variable amounts of ionizing radiation from his natural surroundings. To these he has now added similar radiations from his own inventions. In their biological action these differ but little from each other, and all must be taken into account when assessing the present hazards from ionizing radiation. We shall first consider those inescapable radiations which come from the natural background and, thereafter, those which are derived from sources controllable by man.

190. It will be clear from an earlier chapter of this report that relatively heavy doses of radiation are required to impair the health of the individual and such doses are rarely associated with the ordinary circumstances of civilian life. The use of radiation for medical purposes or occupational exposure to sources of radiation may be associated with the possibility of high doses, but every precaution is taken to safeguard the patient, and the employee is protected by nationally and internationally recognised recommendations which limit the doses received occupationally to levels considered to be safe.

191. On the other hand, our knowledge of the genetic effects of radiation is less precise and it is believed that doses of radiation which have no known effects on the health of the individual may be of genetic consequence. Doses received from all sources, however small, have therefore to be assessed in the light of their possible genetic implications. It has been seen that ionizing radiation can have genetic consequences only in so far as it affects the reproductive organs—the gonads—and it is thus the dose received by the gonads up to the end of reproductive life which must be estimated in all cases. At the levels of dose with which we are mainly concerned, the genetic effects of radiation can be calculated only in relation to the population as a whole. It is therefore in terms of the total gonad dose* to the population that the following estimates of the exposures from various sources have been made

Radiation from Natural Sources

Cosmic radiation

192. Cosmic radiation reaches the earth from interstellar space. The atmosphere surrounding the earth has substance and acts as a filter, absorbing almost all the dose to which otherwise we should be exposed. In general, the longer their path through the atmosphere, the more the radiations will be attenuated; thus, the dose at sea level is less than that at high altitudes.

* The total gonad dose has been calculated on the basis of the considerations set out in paragraph 129.

193. Cosmic radiation has several components—protons,[1] fast and slow mesons,[2] electrons[3] and neutrons[4]—which differ in their relative contribution to the natural background of radiation according to the altitude; at sea level the most important are mesons, electrons and neutrons. Mesons and electrons are considered to be, for equal physical doses, of about the same biological effectiveness as gamma rays. Fast neutrons and protons of high energy may be several times more damaging to the individual but are less likely to induce gene mutation. Neglecting this possible variation in effectiveness and assuming equal biological efficiency for all the particles, one derives a dose at sea level equivalent to 0·028 r per annum from cosmic radiation. Virtually all of this is highly penetrating radiation and can be assumed to irradiate the whole body, including the gonads, almost uniformly.

Terrestrial radiation

194. A few of the naturally occurring elements, particularly the heavy elements, are radioactive, thorium and uranium being the chief primary sources. These two elements are only feebly radioactive and each has a half-life measured in many millions of years. Each atom, in its radioactive disintegration, is transmuted to a daughter atom which is also radioactive and which in turn disintegrates to another radioactive atom, the process being continued until ultimately a non-radioactive stable atom of lead is formed. All the daughter elements decay much more rapidly than the original parents, thorium and uranium, and many of them emit gamma rays as well as nuclear particles in their disintegration.

195. Thorium and uranium are almost universally distributed in trace quantities in rocks and soils, areas of granitic rock usually having higher concentrations than sedimentary rock. Occasionally, the concentration is considerably greater than normal, sufficient to make the area worth mining, but even in these rich lodes it is usually only of the order of one per cent or less.

196. As a consequence of the presence in many soils of the radioactive daughter products of uranium and thorium, emission of gamma rays occurs widely over the land surfaces of the earth. Brick and stone necessarily contain traces of these radioactive substances and, inside houses built of such materials, radiation is added from this source. On the other hand, substantial structures of brick and stone offer slight shielding from cosmic radiation.

197. The amount of radiation contributed from the earth and from buildings varies from place to place even in the same country and any average figure can be only an approximation, but 0·078 r per year would perhaps be representative of the amount received inside buildings on the surface of the body by the inhabitants of this country. The corresponding figure in the open would perhaps be 0·048 r per year. Measurements show that about 37 per cent of the dose of gamma rays is absorbed superficially and filtered off before reaching the internal tissues and organs: allowing for this and esti-

[1] *Protons* are nuclei of hydrogen atoms and carry a unit positive charge. Fast moving protons are a minor component of cosmic rays at ground level. Neutron radiation also ejects protons from hydrogenous material.

[2] *Mesons* are unstable particles with masses intermediate between those of electrons and protons. Energetic mesons constitute the main component of the more penetrating cosmic rays.

[3] *Electrons* are the smallest constituent particles of atoms. The electron carries the elementary negative charge of electricity. It has a positively-charged counterpart of equal mass called the positron. The soft or less penetrating component of cosmic rays consists essentially of positrons and electrons and about an equal number of gamma rays.

[4] *Neutrons*, see Chapter II, paragraph 19.

mating the amount of time that a person spends in the open, the average dose to the gonads of persons in this country from external gamma radiation is estimated to be 0·043 r per year.

Atmospheric radon

198. One of the decay products of uranium is radon, a gas which diffuses out of the earth and buildings and from minerals such as coal. In general, its concentration in the atmosphere is extremely low, about 0·3 of a micro-microcurie* per litre of air, but in cities such as London, where much coal is burnt, it may sometimes reach ten times this amount. In these circumstances, the dose of gamma rays from the further disintegration-products of radon may almost equal the dose of radiation from cosmic sources. The average dose to the gonads from this source, however, probably does not exceed 0·001 r per year from the atmosphere and an approximately equal or slightly greater amount from the gas absorbed into the body from the lungs.

Radioactive constituents of the body

199. Among the normal constituents of the body are the elements carbon and potassium, each of which has a radioactive isotope occurring naturally as a minute fraction of the total element. The radioactive isotope potassium 40 forms 1/8000 of natural potassium and emits both beta particles and gamma rays. An average value for the potassium content of the body is 0·21 per cent by weight, and measurements suggest that the figure for the gonads does not differ greatly. Calculation on this basis gives an estimated dose to the gonads of about 0·02 r per year. Naturally occurring radioactive carbon, carbon 14, constitutes one part in a million millions (10^{12}) of natural carbon; it emits only beta particles. Taking body tissue to be 18 per cent carbon, one derives a dose from this source of about 0·001 r per annum to the gonads.

Total gonad dose from natural sources

200. Information on the total dose to the gonads from natural sources of radiation is summarised in Table 2. It will be seen that, from all sources, the total is roughly 0·1 r per annum, or about 3 r per generation of 30 years (Appendix J).

TABLE 2

Estimated dose rates to gonads from natural sources of radiation

Radiation source	Estimated average dose rate to gonads in roentgens per year
External radiation	
Cosmic rays (sea level)	0·028
Gamma rays from the earth	0·043
Radon in air	0·001
Internal radiation	
Potassium 40	0·020
Carbon 14	0·001
Radon and decay products	0·002
Total	0·095

* $\frac{1}{1,000,000,000,000}$ of a curie.

Radioactivity in bone

201. Within the body, radioactivity is probably highest in bone. The naturally occurring radioactive heavy elements are contaminants of food and water as well as of soil and they and their disintegration products, of which radium is the most important biologically, are absorbed to a very limited extent from the gut. The body removes them from the circulation and stores them in bone. In this way the radioactivity of bone builds up gradually throughout life but there is no evidence that the rather higher doses in bone compared with other tissues are deleterious. Table 3 gives the estimated doses to bone from these sources.

TABLE 3

Estimated radium content and radiation dose rates to bone-cells

Geographical conditions	Estimated radium in skeleton at age 35 in micro-microcuries	Dose rate to bone-cells in equivalent roentgens per year		
		radium	external sources	total
Average areas	60	0·037	0·08	0·12
Active areas ... ... (See Appendix J)	1,100	0·37	0·18	0·55

Radiation from the Appurtenances of Civilisation

202. Since the discovery of X-rays and radioactive materials man has adopted them increasingly for certain of his needs. In medicine they now provide invaluable, and often irreplaceable, aids to diagnosis and treatment. They are also used extensively in industry and in the amenities of modern civilised life. It is necessary, therefore, to assess the dose that these developments contribute above that received from the natural surroundings.

Diagnostic X-rays

203. For some time it has been realised that by far the largest contribution is made by diagnostic X-rays. Continuing efforts are therefore being made to assess the dose of radiation given to the whole population in this way. The problem of accurate assessment is beset with difficulties and at present any estimate must be based upon very imperfect data. The two basic requirements and the best means of fulfilling them from available figures are as follows:

(i) *The number of radiological examinations made annually, subdividea according to the sex and age of the persons examined and the part of the body under examination.* It is possible to make from published figures a reasonable estimate of the total number of X-ray examinations made within the National Health Service. A minimum figure for the year 1955 would be 12,200,000. To this must be added an unknown but relatively small number for hospitals outside the National Health Service and for private practice. This number has been estimated at rather less than half a million, giving a total of 12,650,000.

The division of this very large figure into sex, age and type of radiological examination has been made on the basis of information supplied by five hospitals only and covering some

21,000 patients (two London teaching hospitals and three others). While there are certainly differences between these hospitals, they are not so wide as to make an approximate calculation unwarranted. The sample has therefore been accepted as representative.

A very important source of radiation to the gonads is provided by radiological pelvimetry, which measures the size of the pelvic outlet of the woman in relation to the actual or potential size of her infant; a second important source is X-ray examination of the abdomen in pregnancy. Information of the frequency with which such examinations are made has therefore been specially sought from a rather wider group of nine hospitals. On the assumption that these are representative, the results have been applied to all live births occurring in hospitals in England and Wales.

In addition to the 12,650,000 X-ray examinations already mentioned, certain others are undertaken for special reasons and these bring the estimated total during 1955 up to nearly 18,000,000. The additional examinations include mass miniature radiography, dental radiography, and examinations of service personnel and mineworkers, but each of these types of examination represents a relatively unimportant source of radiation to the gonads and the effect of any error in estimating their contribution will be slight in relation to the total.

(ii) *The average dose to the gonads—male, female and foetal separately—produced by the diagnostic irradiation of each separate part of the body.* For the purposes of calculation the figures used, which cover X-ray examinations of 24 different parts of the body, have been derived almost entirely from one London teaching hospital where careful measurements have been made and precautions taken to restrict the irradiation of the gonads to the lowest possible level. They are therefore almost certain to be minimum figures. It should be realised that with the X-ray tube only slightly misaligned the dose may sometimes be multiplied many times.

204. Bringing together these two sets of figures—the estimated numbers and ages of persons irradiated and the estimated average gonad dose delivered to them with specified examinations—leads to two important general conclusions. It shows, first, that almost the whole population dose is accounted for by a relatively few sites of examination, principally the hip, the lumbar spine, the lower abdomen and the pelvis. The far more frequent examinations of chest, head and limbs make relatively unimportant contributions. Secondly, according to the present calculations, the amount of radiation reaching the reproductive organs of the people of this country through diagnostic radiology is as much as 22 per cent of that derived from natural sources. Indeed, in view of the minimum figures adopted in these calculations, the contribution of diagnostic radiology may well be very considerably higher than 22 per cent. It undoubtedly forms the most important source of man-made irradiation and its application has been steadily increasing in recent years (Appendix K).

Radiotherapy

205. At present there is little information about the contribution to the population dose from therapeutic irradiation. Although its main use is for patients with malignant disease, the majority of whom are beyond the child-bearing age, some younger patients are treated for non-malignant conditions such as ankylosing spondylitis. Less penetrating X-rays are widely used in the treatment of a large number of diseases of the skin, and the artificially

produced radioactive element iodine 131 is now being administered for hyperthyroidism.

206. It is as yet not possible to state a figure for the population dose to the gonads from this source of radiation. Rough assessments would suggest that it is considerably less than the dose from diagnostic radiology but probably greater than that from any other source. The problem is one upon which research is required.

X-ray fluoroscopy for shoe-fitting

207. X-rays are used commercially for fitting shoes but, with modern equipment and good practice, it appears that the number of machines in operation would probably deliver not more than 0·1 per cent of the dose to the gonads received from natural radiation.

Luminous watches and clocks

208. Watches and clocks with luminous dials depend for their luminosity upon the rays from radium or other radioactive material used in the paint. Measurements and calculations suggest that the average wrist-watch contains about one-fifth of a microcurie of radium. A calculated dose to the gonads from wearing such a watch is about 0·01 r per year.

209. From the information given by the trade, it can be deduced that there are in use about three million men's watches and about a million women's and children's watches with luminous dials. In addition, there may be about ten million luminous alarm clocks. On this basis it can be estimated that the population dose from this source is about one per cent of the natural background.

Television sets

210. Cathode-ray tubes for television sets are capable of causing the production of X-rays. In general, however, the operating voltages are comparatively low and the X-rays are readily absorbed by the walls of the tubes and by protective screens. It can be estimated that the population dose from this source is at present much less than one per cent of the dose received from natural radiation.

Cosmic radiation in aircraft

211. Since the amount of radiation from cosmic sources is greater at high altitudes, the doses received by persons in aircraft have been investigated and the population dose calculated. The additional dose averaged over the whole population is at present insignificant compared with that received from the natural background.

Occupational Exposure to Radiation

Medical and industrial workers

212. Men and women have been exposed to ionizing radiation in the course of their occupations for over half a century. In the early years after the discovery of X-rays and radioactive materials many suffered injury, but safe practices have gradually been elaborated and standards of safety laid down. In this country since 1921 the British X-ray and Radium Protection Committee, and later the Medical Research Council's Committee on Protection against Ionizing Radiations, have considered the available information and made periodic recommendations on occupational exposure levels. Equivalent levels have been advocated by the International Commission on Radiological Protection.

213. Control of radiation exposure may be effected in two ways. In the first, the intensity of radiation in the vicinity of the source is measured at frequent intervals and, provided that the intensities are always below those levels accepted by international agreement as being without danger, no separate check is required on the exposure of the individual. In the second, the doses actually received by the individual are recorded, usually by means of a photographic film which he carries and which blackens on exposure to radiation, so allowing the dose received, if any, to be estimated. For twenty years the National Physical Laboratory has provided a service whereby such films are issued on demand and subsequently read. The worker and his supervisor can thus keep a check on the doses received to ensure that the accepted weekly levels of dose are not exceeded.

214. The provision of film badges has now been taken over by the National Radiological Protection Service which serves the majority of people known to be occupationally exposed, other than those employed by the Atomic Energy Authority or in the many hospital departments which process their own films. The Service will be available to those employed in the many and increasingly varied industrial applications of ionizing radiation as well as to research laboratories.

215. The available records have been sampled and analysed to assess the total dose from these sources to the population but, as precise records are not available from all branches of industry, the contributions from some sources are estimates only. It has not been possible to make as accurate an assessment as for the employees of the Atomic Energy Authority because the number, sex and ages of those exposed are not known with any precision and the monitoring, when carried out, is not as complete.

216. On the basis of figures from the hospitals which make use of this service, it has been roughly calculated that about 60 per cent of the medical workers at risk are women; in industry and research, women constitute only 15 per cent. It is estimated that in total about 14,000 people are employed, of whom half are women. After allowance for the fact that in women radiation is more completely absorbed before it reaches the gonads, it is estimated that the average gonad dose for both men and women would be about 2·5 r per year. Because the ages are not known with precision, it is not possible to make an accurate estimate of the genetic dose to the population as a whole, but after making certain assumptions we have reached a figure from this source of 1·6 per cent of natural background radiation (Appendix L).

Atomic Energy Authority employees

217. The Atomic Energy Authority now employs about 7,000 people who are exposed or potentially exposed to radiation in the course of their work. All employees liable to be exposed wear film badges that are examined weekly or monthly, and the sex and age of each individual are known. Thus it has been possible to calculate, with considerable accuracy, the doses received by the employees in relation to their expectation of parenthood. The average dose to the Authority's employees from all occupational sources of radiation is 0·4 r per year. The results of personnel monitoring show that in all recent years no employee has had an average weekly dose exceeding the maximum permissible and that about 90 per cent of the persons exposed to radiation averaged less than one-tenth of the maximum permissible weekly dose. It has been estimated that the gonad dose averaged over the population as a whole is about 0·1 per cent of the natural background.

Contamination of the World by Fall-out from the Explosion of Nuclear Weapons

218. Nuclear weapons differ in their construction and size and the same type of weapon can be detonated in different ways—under water, on land or in the air. These variations lead to differences in the radioactive dust produced, in its distribution and in the rate at which it falls out from the atmosphere on to the earth. Except in the immediate vicinity of a nuclear weapon explosion, the ionizing radiations to be considered arise from radioactive particles.

Radioactive fission products

219. Radioactive fission products, formed when the atoms are split, become mixed with the vapourised material from the bomb and with any earth, water or debris caught up in the explosion. Large particles fall quickly and are deposited close to the site of explosion; small particles are carried up with the hot gases to heights which vary with the power of the explosion. They subsequently travel in air streams for considerable distances and times, depending on the size of the particles and the height to which they were carried.

220. The particles reaching this country from the distant explosion of a typical nuclear weapon detonated over land are spherical in shape and consist of fused silica and metallic oxides impregnated with fission products. The vast majority are smaller than 0·001 of a centimetre in diameter. Particles from the thermonuclear tests in the Pacific atolls differ, in that they consist of calcium oxides or carbonates from coral and are irregular in shape. Both varieties are radioactive.

221. Different types of weapon produce a similar mixture of fission products in slightly different proportions, but the overall rate of decay of radioactivity is almost the same in all types. The total radioactivity decays to one-tenth of the original level for each seven-fold increase of time in days, as measured from the moment of detonation; thus, if the radioactivity is one unit on the first day after detonation, it is 1/10 unit at seven days, 1/100 unit at 49 days, and so on.

222. At the time of atomic explosions some normally stable elements may become radioactive by virtue of the capture of neutrons. Such induced activities are for all practical purposes short-lived and therefore of little importance when long-term hazards are being considered.

223. Since January 1951, continual watch has been kept by the Atomic Energy Authority on the radioactive fall-out reaching this country from nuclear devices exploded in other parts of the world. The activity in rain water at selected sites is recorded continuously. In addition the atmosphere is sampled daily by the collection of dust on a cylindrical filter through which about 1,500 kilogrammes of air are passed, and the radioactivity of the filter papers is determined (Appendix M).

Radioactivity in air

224. When the ordinary type of atomic bomb is exploded in Nevada, the dust-cloud rises to a height of about 40,000 feet. It then travels eastwards with the winds which prevail at that height and diffuses both vertically and laterally. It may or may not pass over this country on its first circuit round the world; if it does so, it will usually appear about 5 days after the explosion. The cloud continues circling the earth, and peaks of activity can be detected over any particular place in its path at about monthly intervals. The total radioactivity per unit volume of air falls progressively with time

owing to decay of the radioactive elements, to increased spread of the cloud and to deposition on the surface of the earth; approximately half the available material is deposited every 22 days.

225. Clouds from thermonuclear explosions behave differently because of the far greater height, approximately 100,000 feet, to which the debris is carried. Diffusion downwards from the stratosphere is a very slow process, and months after a thermonuclear test explosion most of the radioactive debris is still at these great heights.

226. Dust clouds from distant tests passing on the first circuit over this country are usually too high to impart measurable activity to air at ground level. Subsequently, at the peak periods, concentrations are in the region of five radioactive disintegrations per minute per cubic metre (dpm/m^3) of air. From April, 1952, to December, 1955, the mean concentration of activity from all bombs exploded in that period was 0·5 dpm/m^3. The corresponding average activity from naturally occurring radon decay products in the air was measured at one of the sampling stations and found to be 130 dpm/m^3. The debris from the thermonuclear tests in the Pacific in 1954, much of it by now already decayed, has mostly still to come down, but it is not expected to exceed 0·1 dpm/m^3 in the next few years. The dose to a person fully exposed to air with a radioactivity of 0·5 dpm/m^3 has been calculated to be one millionth of a roentgen per year.

Deposited radioactivity

227. The radioactive fall-out is cleared, sooner or later, from the air by deposition. Rain contains the bulk of deposited activity and continuing measurements have been made since 1951 of the radioactivity of rain water collected from specially treated roofs. Any radioactive dust deposited on the roofs in spells of dry weather is washed off and included with the next sample of rainwater. From these measurements the amount of radioactivity deposited per square mile can be determined for each explosion.

228. The dose that a man standing in the open in this country would receive from the deposition of radioactivity from all bombs so far exploded has been estimated. It has been assumed that all the radioactivity remains on the surface of the earth and that none is lost, as we know some will be, by drainage and weathering. Including all ordinary atomic bombs exploded before December, 1955, and calculating all the radioactivity which they have contributed and will contribute over the next 50 years, it is found that the total dose which a man continuously out of doors, night and day, would receive is 0·005 r. To this dose from ordinary atomic bombs must be added the dose from thermonuclear weapons. For these latter the dose from the radioactivity still to be deposited is more important. It can be estimated that the accumulated dose from thermonuclear weapons is 0·002 to 0·003 r with another 0·027 r still to come.

Total radioactivity from weapons already exploded

229. All these doses together add up to about 0·035 r from weapons already exploded. This is a maximum dose. The loss of radioactivity from weathering has not been taken into account, nor has the protection afforded by buildings in and around which most people in this country spend a large part of their lives. It would be realistic to divide the dose by three for weathering and by seven for protection afforded as a result of time spent in houses. The average inhabitant of this country may therefore receive in the next 50 years between 0·001 and 0·002 r from this fall-out, or 0·02 to 0·04 per cent of the radiation that he will receive during the same period from natural surroundings.

230. If the firing of both types of bomb were to continue indefinitely at the same rate as over the past few years, there would be a build-up of activity gradually reaching a plateau in about a hundred years time which, on the same basis of calculation, would give the average individual a dose over a period of 30 years of 0·026 r or about 0·9 per cent of what he would receive in the same period from natural sources.

231. The most impressive feature of these figures for exposure from fall-out is the very great effect of a very few thermonuclear explosions. This is not surprising since their power is measured in equivalents of millions of tons of TNT compared with the thousands of tons for atomic bombs. If the rate of firing this type of weapon increases, the radiation exposure will be altered proportionally.

SPECIAL HAZARDS FROM RADIOACTIVE FISSION PRODUCTS

Particulate contamination

232. The total radioactivity in the air from fall-out is measured daily, and determinations are made of selected individual radioactive substances. The activity will arise from particles which may be inhaled into the lung. It can be calculated, however, that not more than one or two particles of the more highly active substances are breathed by any person in the course of a year (Appendix M). Although the radioactivity of these particles is minute, it is concentrated in a few million-millionths of a cubic centimetre (10^{-12} c.c.) and the possibility of their creating a hazard must therefore be considered. The International Commission on Radiological Protection has concluded that the critical volume of tissue to be taken into account is of the order of one cubic centimetre, which is a larger volume than could be heavily irradiated by a few such radioactive particles. It seems unlikely that particulate contamination of the air from the fall-out from test explosions would constitute a problem in ordinary civilian life.

233. Radioactive material from the air is deposited and accumulates on the ground where it may contaminate drinking water and agricultural crops. After deposition it becomes possible to make routine measurements of the present concentration of the more dangerous radioactive substances. By December, 1955, this concentration amounted to 0·011 curie of strontium 90 and 0·0002 curie of plutonium 239 per square mile. The continuing fall-out from explosions which have already taken place will cause a rise, to a maximum by about 1965, of around 0·045 curie of strontium 90 per square mile. These figures should be viewed against the background of the fact that the top one foot of soil has always contained on the average about one curie per square mile of the equally, if not more, dangerous naturally occurring radium.

Strontium 90

234. From the point of view of general contamination of the world, the hazard from deposited strontium 90 might, according to present ideas, be greater than that from external radiation, since strontium, like radium, is ordinarily retained in the body and deposited in bone. The average concentration of radioactive strontium in rain water over a period of three years ending December, 1955, was 1·7 micro-microcuries per litre and, since most water passes through soil before being drunk, the activity reaching human beings through drinking water is extremely small.

235. Strontium 90 is deposited on herbage and soil and is then absorbed into plants. Man and animals consuming the leaves of plants will therefore receive strontium 90 in food as well as in water. The hazard is greater for

grazing animals than for man, since animals may crop herbage from wide areas of contaminated pasture. Man, moreover, relies for his food more on grains and roots, which are not sites of concentration of strontium, and on animal produce from which the animal has removed most of the strontium to its bones. Cows' milk contains strontium, but fortunately the cow in its metabolic processes secretes calcium into the milk in preference to strontium.

236. The importance of radioactive strontium, compared with other long-lived fission products produced by exploding nuclear weapons, derives from four factors; its relative abundance among the fission products, its facility for following calcium through the human food chain, the ease with which it is absorbed, and the fact that, once absorbed, it is stored for long periods in the bones of the body. In bones it forms more or less localised deposits which, judging by animal experiments and according to analogy with the action of radium compounds on human subjects, can if present in sufficient amounts give rise to bone tumours or, by irradiating the neighbouring bone marrow, to aplastic anaemia or leukaemia. There is evidence that the young are more susceptible to its action than adults. Such measurements as have been made of strontium 90 in human bone suggest that the highest levels are at present about a thousand times less than is considered permissible for those occupationally exposed.

Plutonium

237. Plutonium 239, another very long-lived radioactive element, is also a potentially dangerous contaminant since, like strontium, it is deposited in bone. The amount of activity from plutonium in fall-out is small relative to that of strontium 90, its solubility is low, and less than one-tenth of one per cent of the amount taken by mouth is absorbed. The hazard from plutonium in fall-out debris is thus very small.

Caesium

238. Very sensitive methods of measuring the radioactivity of the human body have now been developed and, on the records obtained in recent months, there has been some indication of gamma radiation suspected to be due to the long-lived fission product caesium 137. Although it is not possible yet to identify with certainty the source of this radiation, calculations have been made on the assumption that it is due to this isotope. Caesium is not concentrated in any particular organ of the body and, on the basis of present information, is unlikely materially to affect the figure given above for the dose from the fission products deposited on the ground.

Other important isotopes

239. Of the other elements in mixed fission products strontium 89 and barium 140 behaves similarly to strontium 90; iodine 131, which is easily absorbed, is highly concentrated in the thyroid gland. These three isotopes, having half-lives which are only a matter of days, are of very little significance in relation to the long-range fall-out from atomic bombs, since most of their radioactivity will have decayed before they are deposited. In relation to the heavily contaminated areas within a few hundred miles of the explosion of a thermonuclear bomb, however, they will be of great importance.

TOTAL GONAD DOSE FROM MAN-MADE SOURCES OF RADIATION

240. Information on the total dose to the gonads from man-made sources of radiation is summarised in Table 4, the dose from each source being expressed as a percentage of the dose received from natural sources. It will be seen that the total dose amounts to approximately 25 per cent of that already received from the natural background.

TABLE 4

Summary of estimated population doses of radiation to the gonads expressed as percentages of natural background

Source of Radiation	Approximate dose to gonads as a percentage of natural background
Natural background	100
Diagnostic radiology	at least 22
Radiotherapy	?
Shoe-fitting	0·1
Luminous watches and clocks	1
Television sets	much less than 1
High altitude flying	insignificant
Occupational exposure:	
Radiology and Industry	at least 1·6
Atomic Energy Authority	0·1
Fall-out from test explosions	less than 1

Nuclear Warfare

241. Atomic bombs were developed for their capacity to create blast, which was the chief cause of casualties at Hiroshima and Nagasaki. The additional effects of the detonation of a nuclear weapon are due to the release of other forms of energy—heat and ionizing radiation. The ionizing radiations produced by the weapons are the new feature of military operations. Of the prompt radiations, produced at the moment of explosion, neutrons are the direct result of the process of nuclear fission. Gamma rays are also a by-product of fission but most of these are produced immediately after the detonation by the enormous quantities of radioactive fission products. The rapid ending of the gamma-flash at ground level after an explosion is due partly to the ephemeral nature of the radioactivities of many of the fission products and partly to the very rapid removal of the debris in the up-draught of hot gases.

242. The effective range of the prompt ionizing radiations from an ordinary atomic bomb explosion is less than that of the thermal radiation, and at Hiroshima and Nagasaki the range within which death and severe injury from ionizing radiations were encountered was about one mile, as compared with up to three miles for severe flash burns and five miles for indirect blast effects.

243. The notable feature of the ionizing radiations is that, in contrast to the heat rays, they are very penetrating. Clothing which may be adequate to shield the body from heat flash is 'transparent' to these rays, and even four inches of concrete transmit half the radiation at a distance of one mile from the atomic bomb burst. Thus, at ranges relatively close to such a weapon, people in stoutly constructed buildings might survive the effects of the heat and blast waves but suffer from the damaging effects of the penetrating gamma rays and neutrons.

244. From the comparative ranges of the heat flash and ionizing radiation it will be seen that distance is a factor of great importance. With gamma-rays, as with heat, the intensity falls in proportion to the square of the distance and is diminished by an attenuation factor. It is unlikely that the prompt radiations from thermonuclear weapons would be relatively more significant than those from atomic weapons. The hazard from radiation is

therefore only one of the immediate effects of nuclear weapon explosions, and a relatively minor one in a holocaust. Its particular importance lies in the delayed and distant effects, which arise from the radioactive fission products.

245. At Hiroshima and Nagasaki the atomic bombs were exploded high in the air so as to obtain the maximum effects from blast. Virtually all the fission products were therefore carried up with the hot gases and must have been enormously diluted before being deposited gradually round the world. However, some did fall to earth locally and presumably contributed to the delayed effects recorded by the Atomic Bomb Casualty Commission.

246. When bombs are exploded in or near the surface of the ground or near the surface of water, much debris highly contaminated with fission products is flung into the air and the large particles are deposited more or less locally. Some of intermediate particle size is carried by the local winds and gradually diffuses and settles down-wind. The best known phenomenon of this character following a test-explosion arose from the thermonuclear device exploded on 1st March, 1954. According to the Press release in February, 1955, of the United States Atomic Energy Commission, the area over which fission products settled to give a radiation dose which might well have been lethal to a man unable to take shelter was about 7,000 square miles. Over a considerably larger area, conditions in the open would have been hazardous to man and beast. The size and shape of these lethal and hazardous areas will vary with the conditions of the explosion and of the local meteorology. Nevertheless, the inferences are plain: weapons such as these can be devastating, not only locally over areas measuring hundreds of square miles, but in their more distant effects, which may occur over thousands and tens of thousands of square miles.

CHAPTER VI

ASSESSMENT OF THE HAZARDS OF EXPOSURE TO RADIATION

247. We have reviewed the effects of radiation both upon the exposed individual during his own lifetime and upon his descendants. It is now necessary to relate these effects to dose levels, and to attempt to assess the consequences of exposure to those levels of radiation which now occur or might conceivably come about in the future.

248. It will be recalled that human beings have always been exposed to radiation from outer space and from traces of radioactive materials in their surroundings and in their own bodies. The problem is, therefore, to assess the effects of any additional radiation to which they are or may be subjected, rather than to define a new experience. Our ignorance of the results of exposure to radiation is great and much intensive research is required in many fields; but the naturally occurring background of radiation to which mankind has long been adjusted can be taken with some confidence as a safe standard of reference, whether we are considering irradiation from outside the body or from radioactive materials taken into the body and stored, temporarily or permanently, in its tissues.

Differences between individual and genetic effects

249. Different considerations enter into the assessment of the significance of any particular level of exposure, according to whether we are concerned with effects on the individual or with genetic effects. In respect of the effects on the individual, we are concerned with doses received throughout the whole of life. In respect of genetic effects, however, we are concerned only with doses to the gonads received up to and during the reproductive period of life. In this country the average age of mothers conceiving children is about 28 years; of fathers, two to four years older. We have therefore taken the period of 30 years to represent the average length of time during which the germ cell lineage of the human population is effectively exposed to radiation. From a genetic point of view, any exposure to radiation after reproduction has ceased is irrelevant, since any mutations produced will not be passed on to future generations.

250. The second important difference relates to the accumulation of the effects of exposure on separate occasions. The genetic effects of radiation are cumulative; a mutation persists once it has been produced in a germ cell lineage, and to this are added any further mutations that are induced in the same reproductive cells. Since dose and effect are proportional, we are concerned, from the genetic point of view, with the total dose of radiation which has been accumulated up to any particular time in the reproductive period of life.

251. The position with regard to the effects of successive doses on the individual is incompletely known. It is certain that a dose of radiation which would produce acute effects if given as one single exposure may produce no similar effects if spread over a longer period. Moreover, if a sufficient period has elapsed after recovery from the acute effects, the individual may again recover from a further exposure which produces acute symptoms. Uncertainty

arises in relation to some important delayed effects of radiation where, in view of the results on the increased incidence of leukaemia in repeatedly irradiated cases of ankylosing spondylitis, we must now entertain the possibility that repeated exposures to radiation may combine to produce certain irreversible changes in the tissues exposed.

Dosage and Effects on the Individual

Acute effects

252. The effects which appear within the first 48 hours are seen only as a result of accidents and in those within a short distance from an atomic bomb explosion, or occasionally after exposure to the heavy doses of radiation which may be necessary in the treatment of serious illnesses by radiotherapy. They are, therefore, not important in ordinary civilian circumstances.

253. The same considerations apply to the acute effects on the blood occurring up to two months after exposure to a single dose or to a few heavy doses of radiation. Similar effects occurring later can, however, be produced by doses of radiation, given continuously or repeated at short intervals, which would not be sufficient to produce any symptoms in the first few hours. Formerly, it was thought that continuous exposure to 1·0 r per week would produce no effects on the blood but, after some individuals were found to be affected by this dose, the figure recommended by national and international bodies as the maximum permissible level was reduced to 0·3 r per week.

Delayed effects

254. Of the delayed effects, the one about which we have most information is leukaemia. It also appears to be the most easily induced and seems, at present, to be the most important as far as radiation of the whole body is concerned. We have therefore taken the incidence of leukaemia as a measure of the doses of radiation that are capable of producing delayed effects. The statistical evidence indicates that an increased incidence of leukaemia can be demonstrated after exposure to doses of radiation which might, in exceptional circumstances, be met with in civil life. For example, after either a single exposure of 200 r, or a few exposures which in total amount to 200 r, there is a noteworthy increase in the small chance of developing this disease. What we do not know for certain is whether there would be an increase if a total dose of 200 r were spread over many years. Be this as it may, however, any risk that there may be from such a dose appears to be within the range of risks of other kinds commonly incurred in industrial and professional life.

255. We consider, therefore, that an individual could, without feeling undue concern about developing any of the delayed effects, accept a total dose of 200 r in his life-time, in addition to radiation from the natural background, provided that this dose is distributed over tens of years and that the maximum weekly exposure, averaged over any period of 13 consecutive weeks, does not exceed 0·3 r. We recommend, however, that the aim should always be to keep the level of exposure as low as possible.

Internal radiation

256. The problem of irradiation by radioactive materials taken into the body is in some ways a more complex and difficult one. The material is often concentrated in a particular tissue, such as bone, where it may give rise to malignant change. Owing to the short distance that the rays from a particular concentration of radioactive material can penetrate the tissues, the dose of radiation is extremely variable from place to place in the body.

Nevertheless, on the basis of the known levels of external radiation that can be tolerated, and of experience gained from the accidental ingestion of substances such as radium, 'permissible' levels of exposure for a large number of radioactive isotopes have been agreed. No single level that comprehends them all can be given, since each isotope emits its own characteristic amount and type of radiation, dies away at its own rate, and is absorbed and excreted at a rate dependent on its chemical form and its method of entry into the body. However, it has now been possible to estimate for many different isotopes the concentrations that it is safe to accumulate.*

Dosage and Genetic Effects

257. Our conclusion in the chapter on genetics was that 'For levels of radiation up to the doubling dose, and even some way beyond, the genetic effects of radiation are only appreciable when reckoned over the population as a whole and need cause no alarm to the individual on his own account'. In other words they are essentially problems for society as a whole, to be assessed in terms of the load of medical care that may, in different circumstances, be imposed on the population.

258. In ordinary circumstances only a small fraction, perhaps one or two per cent, of the hereditary abnormalities which appear in a generation can be attributed to fresh gene mutations. For the offspring of any given parents the risk from increasing the mutation rate is very slight. Nevertheless, if the whole of a large population is exposed to enough radiation appreciably to affect mutation rates, an increase even in this small fraction may add up to a large number of new cases. However, it is only if members of an irradiated group or their descendants intermarry over several generations, and do not mate with the unirradiated population, that there is likely to be a disproportionately greater manifestation of hereditary defects among the descendants. Such an extreme degree of inbreeding is unlikely to occur. A fraction of the community can, therefore, without significant genetic risk to their progeny or harm to the population as a whole, receive doses of radiation which would be likely to have serious effects if applied to the whole population (see paragraphs 185–187).

259. From the genetic point of view, we have therefore to consider radiation dosage under three headings:

(i) The dose which the individual can accept without undue concern about its possible effects on his own progeny.

(ii) The dose which can be accepted by a fraction of the population whose occupation exposes them to more than the dose of radiation received by the ordinary member of the community.

(iii) The dose which can be accepted by the whole population.

Dose to the individual in relation to genetic effects

260. We have concluded that doses up to, and somewhat beyond, the 'doubling dose' need cause no undue concern to the individual as regards his own offspring. Further, we gave reasons for believing that the values for the doubling dose of radiation for human genes may be, in general, in the range of 30 r to 80 r. We consider, therefore, that an individual could

* Precise data for a large number of isotopes are given, for example, in the Recommendations of the International Commission on Radiological Protection (1955) (*Brit. J. Radiol.*, *N.S.*, Suppl. No. 6).

reasonably accept a total dose to the gonads of not more than 50 r from conception to the age of 30 years, in addition to that received from the natural background. There will be no undue risk to the offspring of parents over this age provided the rate of exposure laid down in paragraph 255 is not exceeded.

Dose to occupationally exposed groups

261. Similar considerations apply to groups of the community whose occupation exposes them to more than the usual dose of radiation. Provided that such groups do not in aggregate total more than one-fiftieth of our population, we consider that all their members could each safely receive a total gonad dose of up to 50 r from conception to the age of 30 years, in addition to that received from the natural background.

Dose to the whole population

262. In the chapter on genetics we tried to give an indication of the load on the community that might be imposed by a doubling of mutation rates. It will be generally agreed that such a load should not voluntarily be accepted. In relation to genetic changes in the whole population, the significant figure is the total gonad dose of radiation which is received by all those capable of reproduction. A relatively high dose to a fraction of the population can only be offset by a correspondingly low dose to the remainder. If, therefore, we are to contemplate the possibility—and the necessity to develop the beneficent uses of atomic energy and ionizing radiations forces us to do so—that a significant fraction of our population may in future be allowed to receive doses of radiation of a similar order to the doubling dose, then it becomes additionally important to ensure that the dose of radiation to the rest of the community shall be held at the lowest possible level.

263. In view of the inadequacy of present knowledge, however, we do not feel justified in naming any specific figure as a limit for the average exposure of the whole population. It is nonetheless highly desirable that such a figure should be named as soon as possible and we understand that the International Commission on Radiological Protection has this matter under consideration. In the meantime, we feel bound to state our opinion that it is unlikely that any authoritative recommendation will name a figure for a permissible radiation dose to the whole population, additional to that received from natural sources, which is more than twice that of the general value for natural background radiation. The recommended figure may indeed be appreciably lower than this; and we consider that those on whom rests the responsibility for authorising the development and use of sources of ionizing radiation would be well advised to keep this possibility in mind.

The Hazards from Radiation

264. In the light of these general criteria, we may now proceed to examine the various hazards, actual and potential, to which the population in a country like our own may be exposed in consequence of the increasing use of ionizing radiation. In doing so, it will be necessary to distinguish between the hazards of peacetime experience and those which may be encountered in war.

PEACETIME HAZARDS

265. The development of modern civilisation has led to the increasing use of processes which produce radiations. Its future progress will come to depend, to an ever increasing extent, upon their further exploitation in power production, in industry, in medicine and in agriculture, as well as in basic

scientific research. It would be impossible to abolish their use without denying ourselves services upon which we have already come to rely; and, in the future, nuclear energy will constitute a major, if not the most important, physical factor upon which our civilisation will depend. In assessing the hazards consequent upon its use, it is therefore necessary to maintain a sense of perspective and to weigh, as society has done in the case of steam-power, electricity and the internal combustion engine, the risks entailed against the advantages to be gained from the employment of this newer source of power. The risks are twofold: those to the individual and those to the population as a whole. In regard to the former, we may indicate our own assessment by saying that, in view of the small numbers likely to be employed in atomic power production and of experience already gained in the effectiveness of protective methods, it seems probable that a given amount of power might be made available to the community at a smaller cost in accidents, illness and disability than that involved in present methods of mining and power production. The novel aspect of the situation lies in the possible genetic risk to the community as a whole. The considerations which we have put forward suggest that, although this is at present small and seems unlikely ever to be large, it is potentially important. We propose now to indicate the relative hazards of particular uses and to point out where and how these may be expected to increase or should be curtailed.

266. In the chapter on exposure levels, the contributions of the various man-made sources of ionizing radiation to the total exposure were expressed as percentages of the radiation received from natural sources; and it was shown that today the population of this country receives, from man-made sources, a dose of radiation equivalent to at least one-quarter of that from the natural background. In itself this figure, which amounts to less than 1 r over a period of 30 years, can give rise to no immediate apprehensions; but its significance should not be disregarded. From the point of view of population genetics, all extra radiation is undesirable, and it is at least a portent that, in the half century following the discovery of ionizing radiation, man has increased his exposure levels by about 25 per cent. It does not therefore seem to be too early to suggest where the use of ionizing radiation might be restricted.

Medical diagnostic radiology

267. The greatest contribution in this country to the increased exposure to radiation comes from medical diagnostic radiology, the application of which has been steadily increasing in amount and scope in recent years. A large proportion of the genetically significant dose derived from diagnostic radiology is contributed by relatively few types of examinations, of which fluoroscopic and radiological examination of the female pelvis, and examinations of the hip joint and lumbar spine in males, are important examples. Clearly, the small genetic risk to the community and to individuals must be weighed against the possible great advantage and even necessity of the radiological examination to the particular patient. The final decision must be made on medical grounds. There can, however, be no doubt that the risk could in many instances be reduced, not only by a reduction of the actual number of examinations carried out on young people, but also by the use of modern methods of X-ray examination and by strict limitation of the X-ray beam to those parts of the body which have to be exposed. From the point of view of the dose distributed over the population as a whole, and from the point of view of the special risks to individuals associated with examinations involving heavy exposure, we are of the opinion that the time has arrived for a review of present practice in diagnostic radiology.

Radiotherapy

268. The dangers associated with the heavy exposures employed in radiotherapy are well recognised, and the illnesses for which it is used are usually so serious that the risks can be fully justified. In addition, many of the patients treated for cancer are of an age when the genetic risk will be small. Nevertheless, treatment by radiotherapy of certain non-malignant conditions, particularly in children, could with advantage be reconsidered from the point of view of reassessing the risks entailed against the benefits conferred.

269. The increasing use of therapeutic amounts of radioactive isotopes must also be carefully assessed and controlled, although at the present time the total used is probably of little practical significance from a genetical point of view. Should, however, their use become widespread in relation to common diseases of early or middle life, they might make a significant contribution. The risks from the use of 'tracer' amounts of radioactive substances in diagnosis and investigation are at present very small.

Occupational exposure: Atomic Energy Authority employees

270. For a number of years the main group of persons exposed to radiations were workers in the X-ray and radium departments of hospitals. Later, this experience was supplemented by careful observations of those employed in atomic energy projects and the various atomic industries. We have already seen that, as a result of all this experience, the maximum permissible level of radiation for workers was fixed at 0·3 r per week, and this figure is still regarded as a satisfactory working level provided that it is not maintained for years on end. There is, however, no large factor of safety in this figure and, as we have seen above, other limitations are needed for those exposed over very long periods of time. The excellent practice of the Atomic Energy Authority, now the main industrial employer of persons occupationally exposed to radiation, is shown by their record that the average exposure of their employees is less than half a roentgen yearly, and that their contribution to the population gonad dose is only about 0·1 per cent of that contributed by the natural background. These, however, are average doses; but, even if one takes the maximum exposure of those employees engaged in special tasks, this has only occasionally and for short periods approached the maximum permissible dose of 0·3 r per week. In view of the expected development of atomic energy as a source of power, this evidence of the awareness of the risk, and of the care with which it is being met, gives justifiable grounds for reassurance.

Radioactive effluents

271. Concern has been expressed about the possible emission from some nuclear reactors of radioactive particulate matter, which on inhalation might lodge in the lungs and give rise ultimately to cancer. This possible risk is well recognised and has been effectively dealt with.

272. Similar concern has been felt about the disposal of radioactive wastes. It is true that the amounts of radioactive material involved are formidable, but by treatment, by long-term storage to allow of decay, by concentration to relatively small bulk and subsequent burial in sealed containers or disposal in the depths of the ocean, there seems no reason to doubt that this problem can continue to be solved. In this country strict control of the hazard is exercised by legislation.

Occupational exposure: hospital employees

273. The handling of large quantities of radioactive isotopes in the treatment and investigation of patients in hospitals raises many difficult problems

but, with adequate care and training of the workers concerned, experience shows that the doses received can be kept down to one-tenth or less of the maximum permissible levels.

274. In this country a code of practice, formulated by the Ministry of Health on the advice of the Medical Research Council, has been drawn up for the National Health Service. This lays down the relevant permissible levels of exposure as well as giving instructions and suggestions for the implementation of these in practice.

Other industrial employees

275. The control of radiological hazards in non-atomic industry will be more difficult to codify owing to the wide variety of circumstances in which ionizing radiations are used. Measurements of the doses received by many workers are made periodically, but it is difficult to avoid the impression that industrial personnel are, in general, less aware of the hazards of radiation than those engaged in the fields of medicine and atomic energy. The record of the Atomic Energy Authority shows the standard that is attainable and the practicability of being satisfied with nothing less.

Definition and review of safety standards

276. All these problems are under close and continuous scrutiny. Expert national committees, notably those of the Medical Research Council and Ministry of Health, work in close conjunction with international bodies such as the International Commission on Radiological Protection (itself associated with the World Health Organization), so that a wealth of experience is brought to bear on all these problems, and the standards of safety are under constant review.

Miscellaneous sources of radiation

277. There are several other sources of radiation which at present contribute only very small amounts but which cannot be disregarded. The practice of routinely examining the feet by X-rays when fitting shoes is of dubious value and, in view of the possibilities of multiple exposures to children, may even be dangerous. On the basis of avoiding any unnecessary exposure, it is in our view hardly justifiable. We hope that the procedure will be abandoned, except when prescribed for orthopaedic reasons.

278. The contribution of radiation from watches and clocks with luminous dials is also small but real. The main hazard is to workers in the luminising industry but the risk from the widespread use of such instruments is not entirely negligible. We recognise that there are circumstances which require the use of instruments with self-luminous dials. For the majority, however, there is no such necessity and their wider use constitutes an avoidable, if small, risk which could be minimised for all concerned if the amount of radioactive material in these instruments was reduced to the lowest possible level.

279. It has been recognised that television sets give rise to very small amounts of X-rays, but at the present time radiation from this source does not constitute either a personal or a significant genetic hazard. This applies to domestic sets working at normal operational voltages but, near special types of high voltage projection equipment used commercially, the radiation may reach significant levels, although it is improbable that in practice any operator would be appreciably exposed. Nevertheless, the possibility of television equipment giving rise to radiations should be borne in mind when

considering the design and operation of such instruments. So far as sets used by the general public are concerned, most of the radiation is normally absorbed in the apparatus itself and is insignificant at the usual viewing distances.

Test explosions of nuclear weapons

280. It is impossible to explode a nuclear weapon without liberating radioactive matter into the atmosphere. As described in the chapter on exposure levels, the radioactive material diffuses all over the world and in the course of time is gradually deposited on the surface of the earth and comes into contact with human beings. Continuation for an indefinite time of testing at the same rate as over the last few years would gradually increase the contamination of the atmosphere, until in about 100 years time the average individual in this country would receive a dose of external radiation to the gonads of 0·026 r in 30 years of his life, an amount which represents only one per cent of that received from the natural background. The individual and genetic effects of such a dose of external radiation would be insignificant.

281. Account must be taken, however, of the particular hazard from radioactive strontium in the fall-out. The maximum permissible level of strontium 90 in the human skeleton, accepted by the International Commission on Radiological Protection, corresponds to 1000 micro-microcuries per gramme of calcium. But this is the maximum permissible level for adults in special occupations and is not suitable for application to the population as a whole or to children with their greater sensitivity to radiations and greater expectation of life. It is known that radiostrontium is more heavily concentrated in the bones of young than of adult animals, and the few measurements on human bones indicate that at the present time those of children contain about ten times the concentration found in those of adults. We consider, therefore, that the maximum allowable concentration of radiostrontium in the bones of the general population, with its proportion of young children, should not be greater than 100 micro-microcuries of strontium 90 per gramme of calcium.

282. In this country, measurements on human bones of the radiostrontium content, derived from the nuclear explosions that have already occurred, show that the irradiation from this source is now reaching about one-thousandth of the maximum permissible occupational level; and calculation of the fall-out likely to come, if the present rate of firing continues, suggests that this level may be increased ten-fold in the course of several decades. The present level would produce no detectable increase in the incidence of ill-effects. It is evident, however, that we are now accumulating radiostrontium at an appreciable rate and that a close watch will need to be kept on this increase.

283. In the light of knowledge at present available, we should feel that immediate consideration were required if the concentration in human bones showed signs of rising greatly beyond one-hundredth of that corresponding to the maximum permissible occupational level.

284. We are well aware of the inadequacy of our knowledge of the biological effects of radioactive strontium and of the urgent necessity to obtain further information. Nevertheless, recognising all the inadequacy of our present knowledge, we cannot ignore the possibility that, if the rate of firing increases and particularly if greater numbers of thermonuclear weapons are used, we could, within the life-time of some now living, be approaching levels at which ill-effects might be produced in a small number of the population.

285. The general conclusion to be drawn from a consideration of the hazards inseparable from the application of ionizing radiations in peacetime is that at present there is no cause for alarm ; but that, as all such radiations are potentially dangerous, their use should be the subject of constant and close scrutiny, and that adequate justification should be required for their employment on however small a scale. There is a limit to the amount of radiation which any population or any individual can accept and we cannot afford to expend, without careful forethought, the margin which is now available to us.

WARTIME HAZARDS

286. We have given a brief résumé of the effects of nuclear warfare. From this it will be seen that there are three broad categories of effect: those within the range of the actual explosion, those within the contiguous area in which radioactive fission products settle, and world-wide effects due to the contamination of the atmosphere.

287. Within close range of the explosion, nuclear radiations are but one element in the destructive effect. Blast and heat would be of major and probably of more immediate importance in producing casualties but survivors, unless heavily sheltered, would have been exposed to such an intensity of radiation that they would be at risk of developing each and all of the effects that we have described.

288. Explosions of atomic weapons always give rise to radioactive fission products, the heavier particles of which settle in the vicinity. With a ground burst of a thermonuclear weapon, the area of intense fall-out may cover hundreds of square miles. Within this area, those who were not in shelter, and did not remain under cover until the radioactivity of the fall-out had decayed substantially, would be exposed to intensities of radiation sufficient to produce the effects described in all grades of severity. Outside this area, there would be another zone, measured in thousands of square miles, where significant intensities of radiation would occur and where a proportion of those exposed would be at risk of serious consequences.

289. It must be emphasised that these doses, from the point of view both of the individual and of the general population, are several thousand times greater than those we have considered as possible peacetime hazards.

290. The importance of the effects of atomic warfare which would be relayed through contamination of the atmosphere to parts of the world remote from the actual conflict, would depend upon the number and type of bombs exploded. Given a sufficient number of bombs, no part of the world would escape exposure to biologically significant levels of radiation. To a greater or less degree, a legacy of genetic damage would be incurred, and an increased incidence of delayed effects on the individual would probably be induced. Although it is difficult to imagine the general occurrence of radiation intensities which would eliminate the entire human race, atomic warfare on a large scale could not fail to increase for many generations the load of distress and suffering that individuals and all human societies would be called upon to support.

CHAPTER VII

SUMMARY

291. The future development of civilisation is bound up with the exploitation of nuclear energy. Its use, like that of other sources of energy, entails risk, but the risk is controllable and, within limits, can be accepted. It is the scale and not the nature of the hazard that is new, for human populations have always been exposed to natural radiation of low intensity. (Paragraphs 1–14.)

THE NATURE OF RADIATION AND ITS ACTION ON LIVING CELLS

292. Ionizing radiations are so described because they cause the formation of electrically charged particles, ions, in the matter through which they pass. The common types of penetrating radiation are X-rays, gamma rays, alpha and beta particles, and neutrons. Alpha particles cannot penetrate tissue beyond a fraction of a millimetre but gamma rays, and X-rays produced by extremely high voltages, can traverse the whole body. (Paragraphs 15–20.)

293. The biological effects of radiation are related to the intensity of radiation and to the period of exposure. The basic unit of radiation dosage which has been generally used is the roentgen (r). All living tissue can be killed if exposed to sufficiently high doses of radiation. The effects of dosages below those which damage tissues irretrievably may be modified by processes of healing, so that the response to a dose of radiation which is spread over a long time may be much smaller than, or quite different from, the response which would occur if the same dose were given in a very short time. This does not apply to the important type of genetic effect, called gene mutation, produced by the irradiation of reproductive cells, the consequences of which are cumulative and irreversible. (Paragraphs 21–27.)

THE EFFECTS OF RADIATION ON THE HEALTH OF THE INDIVIDUAL

Sources of information

294. Our knowledge of the effects of ionizing radiations on human beings comes from four main sources: from the uses of X-rays and radium in the treatment of disease, mainly of cancer; from a study of the occupational hazards of medical radiologists, workers in the luminising industry, and miners of radioactive ores; from a study of the victims of atom bomb explosions; and from experiments on animals. (Paragraphs 28–34.)

The harmful effects of radiation on man

295. Almost all the effects of ionizing radiation on tissues are essentially deleterious. The benefits to the individual patient of the eradication of a malignant tumour by radiotherapy result from selective damage to the tumour cells. The nature and severity of radiation injury is determined by the type and dosage of radiation received, the part and extent of the body irradiated, the length of the period of exposure, and the age of the persons exposed. The harmful effects may be classified into those which develop within a few weeks of exposure, and delayed effects which may not make their appearance until many years after exposure. (Paragraphs 35–42.)

Effects occurring within a few weeks of exposure

296. The effect of exposing the whole body to a single dose of gamma radiation of the order of 500 r is such that all the persons so exposed would develop acute illness and at least half would die. In civil life, exposure to such a dosage could occur only under the most exceptional circumstances. With smaller single doses, for example of 100 r, not more than 15 per cent of an exposed population would suffer acute illness and very few, if any, of those affected would die. After a single dose of 50 r, acute illness would be very rare. The relationship between the dose of radiation received and the effects that may be produced within a few weeks of exposure is not one of strict proportionality; with each successive and equal increment of dosage the response increases by a progressively greater amount, at least until very large changes have been produced. (Paragraphs 43–50.)

The delayed effects of radiation

297. Delayed effects of exposure to radiation may occur at any time after the end of the second month. Disorders of the skin and underlying soft tissues and of bone may occur and there may be subsequent development of cancer. Cataracts, severe anaemias and leukaemia have been caused and there is evidence from animal experiments that exposure to radiation may cause death at a prematurely early age. (Paragraphs 51–52.)

Leukaemia

298. Leukaemia is a disease in which there is an uncontrolled over-production of white blood corpuscles. Experiments on animals have shown that the incidence of leukaemia is increased by irradiation. Clear evidence that the same is true of man comes from two main sources: a study by the Atomic Bomb Casualty Commission of the incidence of leukaemia in Hiroshima and Nagasaki, and a survey under our sponsorship of the incidence of leukaemia among patients treated by radiation for ankylosing spondylitis. (Paragraphs 53–55.)

299. Ninety-one proven and fourteen suspected cases of leukaemia have been recorded in Hiroshima and Nagasaki between 1947 and 1954 among those present at the time of the explosion and still resident in the cities; the expected incidence in an unexposed but otherwise comparable population is twenty-five. The difference is greater than would be attributed to chance. Moreover, there was a much higher frequency of occurrence among those who had developed early acute radiation illness and among those who had been nearer to the centre of the explosion. The latent period, that is the average length of the period between the explosion and the first appearance of symptoms of leukaemia, was about six years. The evidence suggests that with this type of exposure to radiation the likelihood of developing leukaemia, after its initial rise, remains approximately constant up to at least the ninth year. (Paragraphs 56–61.)

300. Ankylosing spondylitis is a disease in which the joints, particularly those of the spine, progressively lose their freedom of movement. In the treatment of this condition very extensive areas of the body are exposed to irradiation. The records of between 13,000 and 14,000 patients, who had been treated with X-rays between 1933 and 1954, have been studied. Up to 1955, thirty-eight of these patients developed leukaemia, an incidence which, although only about one-third of one per cent, is about ten times greater than the normal expectation. No increased incidence of leukaemia was found among 400 patients who had not been treated by irradiation, but the number is too small to exclude completely the possibility that ankylosing spondylitis

may of itself predispose its sufferers to leukaemia; nor can the possibility be excluded that these patients are more liable than the average person to develop leukaemia after irradiation. Nevertheless, there is clear evidence of a correspondence between the dosage of radiation received and the incidence of leukaemia. The average length of the latent period between the first exposure to X-rays and the diagnosis of leukaemia was about six years. (Paragraphs 62–69.)

301. The conditions of exposure to radiation in Hiroshima and Nagasaki, and in the treatment of ankylosing spondylitis, are not comparable with the irradiation in small doses over long periods which might be received by persons engaged in work with a possible radiation hazard. Some evidence has been presented suggesting an increased death rate due to leukaemia among radiologists but our knowledge of the occurrence of leukaemia under conditions of chronic exposure is too scanty to allow any reliable conclusions to be drawn. (Paragraphs 70–71.)

Cancers

302. Two characteristics of cancers induced by radiation are noteworthy: the tendency of tumours to arise in tissues already severely damaged by radiation, and the long latent period, twenty years or more, before they appear. (Paragraph 72.)

303. A study of the pitchblende miners of Schneeberg and Joachimsthal suggests strongly that inhalation of the radioactive gas radon may lead to cancer of the lung. The latent period has been put at seventeen years and the dosage to the lungs over that period at about 1000 r and in some parts of the lung much higher. In theory, the inhalation of radioactive particles in the fall-out from atomic explosions or in the vicinity of nuclear reactors could also lead to cancer of the lung, but the former hazard is extremely unlikely in peacetime, and steps are always taken to ensure that the latter does not occur. (Paragraphs 73–76.)

304. Radium, mesothorium, plutonium and radioactive forms of strontium are accumulated by and retained in bone. Until the enforcement of stringent controls, cancer of bone occurred among workers in the luminising industry as a result of swallowing radium-containing paint. The latent period was more than fifteen years. (Paragraphs 77–82.)

305. Cancer of the skin was the earliest form of radiation-induced tumour to be described in man. By 1911, before the adoption of modern safeguards, fifty-four cases had been described among the pioneers of radiology. The doses of radiation which have led to the formation of skin cancers must have been several thousand r. (Paragraphs 83–84.)

306. Cancer of the thyroid gland in children has been a sequel to irradiation of the neck for enlargement of the thymus gland. This form of cancer is distinguished by its short latent period (about 7 years) and the comparatively low dosage of radiation required to induce it. However, it is not unlikely that other factors are involved here in addition to the direct effect of irradiation. (Paragraphs 85–86.)

Other delayed effects

307. A fall in the number of red cells and white cells in the blood may follow exposure of the whole body to even moderate doses of gamma radiation. If not detected in time a condition known as aplastic anaemia may occur. (Paragraphs 87–88.)

308. Cataract formation is known to have been caused by neutron irradiation, but for all practical purposes the production of cataract by X-rays is not an occupational hazard. (Paragraphs 89-90.)

309. Delayed effects of radiation on the skin extend from a temporary loss of hair after local dosages of 300r–400r to severe and permanent damage after local exposure to single dosages of 1500r or more, or to repeated doses totalling 4000r or more in a number of weeks. It is in the skin damaged by these higher doses of radiation that tumours, when they occur, are most likely to develop. (Paragraphs 91–92.)

310. Miscarriage and stillbirth may be a consequence of irradiation during pregnancy, but they do not constitute a problem unless the dose of radiation is large. A number of different developmental abnormalities have been described in the children of women treated by irradiation during pregnancy, the most conspicuous defect being microcephaly, a partial failure of the development of the brain. Eleven cases so classified are recorded in children irradiated before birth in Hiroshima and Nagasaki.
(Paragraphs 95–97.)

THE GENETIC EFFECTS OF RADIATION

311. The assessment of the genetic effects of ionizing radiations is subject to special difficulties. We believe that we have formed as fair an assessment as is possible in the light of present knowledge, but our conclusions must be regarded as provisional. (Paragraph 100.)

The material basis of heredity

312. The physical determinants of heredity are genes, carried on chromosomes in the nuclei of cells. Chromosomes are present in pairs; one member of the pair is of maternal origin, the other of paternal origin. There are twenty-four pairs of chromosomes in human beings; the number of genes is not known, but may well be many thousands. (Paragraphs 101–103.)

313. The two genes which occupy corresponding positions on the two chromosomes of a pair are spoken of as alleles of each other. Alleles of different kinds arise by the process of mutation and are thereafter reproduced faithfully in their altered form. (Paragraph 104.)

314. Some genes produce the same effect whether they are paired with like or with unlike alleles. Such genes, and the characters they determine, are described as dominant. Other genes produce a noticeable effect only when paired with similar alleles; these, and the characters they determine, are described as recessive. There is every gradation between these two extremes. A recessive gene can be transmitted in a family by an individual who gives no signs of carrying it. (Paragraphs 105–108.)

315. Sex difference is determined by a special pair of chromosomes, and the genes carried on these chromosomes are said to be sex-linked.
(Paragraph 109.)

316. So far as is known, all genes are subject to mutation, and mutation occurs spontaneously all the time at a very low rate. Factors influencing mutation appear to affect only the frequency with which it happens. New alleles of harmful effect are eliminated by natural selection until equilibrium is reached with the rate at which they are introduced by fresh mutation. Recessive alleles are eliminated much more slowly than dominant alleles.
(Paragraphs 111–118.)

Basic principles of the genetic effects of radiation

317. There is little direct knowledge of the genetic effects of ionizing radiations on man, but with certain reservations it is justifiable to draw upon our knowledge of the effects of radiation on other organisms.
(Paragraph 119.)

318. Ionizing radiations have genetic consequences only in so far as they affect the reproductive cells or the cells ancestral to them in the reproductive organs (gonads). Two kinds of effect may have genetic consequences: the chromosomes may be damaged or the genes may be caused to mutate more frequently. Chromosome changes of the kind that can persist are only rarely produced by long continued exposure to X-rays or gamma rays of low intensity. They are likely to be a comparatively unimportant radiation hazard. (Paragraphs 120–125.)

319. It is the frequency of gene mutation that is increased by radiation; there is no evidence and little likelihood that radiation produces entirely new kinds of genes. The rise in mutation rate is probably directly proportional to the amount of additional exposure to radiation, and any additional exposure, however small, must be expected to raise the mutation rate, if only by a minute amount. (Paragraphs 126–127.)

320. Damage to genetic material is cumulative and irreparable. Long continued exposure to radiation of low intensity induces as much gene mutation as a single exposure to an equal dosage of radiation of higher intensity.
(Paragraph 128.)

321. The age-distribution of those exposed to radiation has an important bearing on the future consequences of its effects. The genetic consequences of the irradiation of individuals beyond the age of reproduction are of course nil. (Paragraph 129.)

Effects of increased mutation on the incidence of disease in human populations

322. The role of heredity in the production of disease ranges from that of a predisposing to that of a preponderating cause. The effects which might be expected to result from an increase in mutation rates can most easily be calculated for diseases known to be caused by single genes, but for relatively few such diseases have we sufficient evidence of the kind upon which such a calculation must be based. (Paragraphs 130–135.)

323. Achondroplasia, haemophilia, and phenylketonuria have been taken as examples of diseases believed to be caused by single genes. If the mutation rates of these genes were to rise to, and remain at, twice their present values, the incidence of the diseases for which they are responsible would ultimately, though at very different rates, rise to nearly twice their present frequencies. Calculations suggest that the incidence of achondroplasia, a dominant form of dwarfism, would rise 80 per cent above its present value in a single generation; haemophilia, a sex-linked disease, would take about six generations to rise by 90 per cent in frequency; and phenylketonuria, a recessive disease associated with severe mental deficiency, would take more than fifty generations to increase its frequency by one half. (Paragraphs 136–139.)

324. Mental diseases, the most important single category in which hereditary causes are known to be important, account in all for nearly half the hospital beds provided in this country. There are grounds for believing that a doubling of the mutation rates of the genes concerned with their causation would, in one generation, increase the frequency of low-grade mental deficiency by three per cent, and of the two principal types of mental illness,

schizophrenia and manic depressive reaction, by about one per cent. If the mutation rates were to remain at twice their present values, the incidence of mental diseases might on the most pessimistic assumptions double also, but would only attain this value after very many generations.

(Paragraphs 140-150.)

325. When all serious illnesses with a hereditary element in their causation are taken into account, it is unlikely that the burden put upon society by a doubling of mutation rates would exceed by more than a few times the contribution made by the increase of mental disease.

(Paragraphs 151–154.)

326. It must be remembered that a harmful recessive gene gives no outward evidence of its presence until chance brings it together with another of its kind. The crop of newly mutated recessive genes caused by an increase of mutation rates could cause suffering over many generations.

(Paragraphs 155–156.)

Hereditary traits showing continuous variation about the normal

327. Most of the variation between human beings is not of the sharp kind that can be traced to the action of single genes. Characters such as physique, intelligence and length of life vary over a wide range by imperceptible gradations, and the hereditary portion of this variation is believed to be due to the combined action of many genes. (Paragraphs 157–159.)

328. The basic effect of an increase in mutation rates upon such characters, here exemplified by scores in intelligence tests, will be to increase the numbers of the more extreme types at the expense of the more average individuals. A doubling of the mutation rates for a few generations would be expected to have only the most trivial effect upon their variation. The effect of a permanent doubling of the mutation rate would be, at most, to double the variation, and this would take hundreds of generations to achieve.

(Paragraphs 160–161.)

Observations on populations exposed to radiation

329. Three direct studies have been made on the children of human beings who have been exposed to ionizing radiations. Two, on the children of American radiologists, were for a variety of reasons inconclusive; the third is the extensive study made by the Atomic Bomb Casualty Commission on the children of those who were in Hiroshima and Nagasaki when the atomic bombs exploded. All three studies are limited to observations on the first generation, so that little genetic effect would yet have become manifest even if the mutation rate had increased. (Paragraphs 162–166)

330. The evidence assembled in the report of the Atomic Bomb Casualty Commission is beset by many difficulties of interpretation, but we believe that it reveals, in the children of those who were the more heavily exposed, a slight but significant change in the sex ratio at birth which might be due to genetic damage. From the nature of the evidence a doubling of the rate of incidence of congenital malformations, or a 50 per cent rise in the stillbirth rates, might have escaped detection if either had occurred. The evidence does not allow us to make any useful estimate of the radiation dose which doubles the mutation rate in man. (Paragraphs 167–170.)

The 'doubling dose' in man

331. An assessment of the sensitivity of human genes to radiation is particularly difficult. Any such estimate should be based upon a sample of genes large enough to be representative of all the effects they exercise, for it cannot be assumed that all genes are equally radiosensitive, nor that the

proportion of the spontaneous mutation rate which can be attributed to natural radiations is the same for different genes. (Paragraphs 171–175.)

332. If all mutations were indeed due to radiation, then the dosage which doubled their frequency would be expected to be equal to that received from natural sources, namely, a dosage to the gonads of about 3 r in thirty years. The available evidence suggests, however, that the percentage of human mutations that are caused by natural radiation might lie between 2 per cent and 20 per cent, and if this is so the doubling dose will lie between 15 r and 150 r. (Paragraphs 176–181.)

333. The direct estimates which have been made of the doubling doses for a variety of plants and animals mostly run from 25 r upwards. It is true that none of the more fully investigated organisms has a lifetime comparable with man's, but there are theoretical grounds for believing that the organisms with the longer pre-reproductive periods might be expected to have the less radiosensitive genes. (Paragraph 182.)

334. The evidence at our disposal, though far from adequate, leads us to conclude that there is rather little likelihood that the real value for the doubling dose for human genes lies between 3 r and 15 r; and that, although we cannot exclude the possibility that for some human genes the doubling dose may be less than 30 r and for others more than 80 r, the best estimate that we can make in the light of present knowledge, is that the value in general lies somewhere between 30 r and 80 r. (Paragraph 183.)

335. Even if the doubling dose were as low as the minimum we can reasonably entertain, namely 15 r, it is extremely improbable that in times of peace more than a small fraction of the population could receive an extra dose of this size. The prevalence of naturally-occurring hereditary abnormalities is such that, if comparatively few individuals received such a dose, there would be no noticeable effect on their immediate offspring or on their descendants even over several centuries. For levels of radiation up to the doubling dose, and even some way beyond, the genetic effects of radiation are only appreciable when reckoned over the population as a whole, and need not cause alarm to the individual on his own account. (Paragraphs 184–188.)

EXISTING AND FORESEEABLE LEVELS OF EXPOSURE TO RADIATION

336. Doses of radiation which are of no known significance to the individual may have genetic consequences. Exposure levels must therefore be expressed in terms of the total dosage to the gonads received by the population as a whole during the period of reproductive life. (Paragraphs 189–191.)

Radiation from natural sources

337. The natural sources of radiation are cosmic rays and the naturally-occurring radioactive elements. From all such sources an individual in this country receives, on the average, a total gonad dose of about 3 r over a period of thirty years. (Paragraphs 192–201.)

Radiation from the appurtenances of civilisation

338. Over the past sixty years man has made increasing use of X-rays and radioactive materials in medicine, industry, and ordinary civil life. The additional gonad doses received from these sources by people of this country are expressed as percentages of the gonad dose which they already receive from natural sources. (Paragraph 202.)

339. We have conducted a limited survey which suggests that the additional dose received from the various forms of diagnostic radiology may well

be higher than 22 per cent, the major amount of which is accounted for by examination of a relatively few sites of the body. The contribution made by the use of radiation in medical treatment cannot be accurately estimated; it is probably much less than that made by diagnostic radiology but greater than that received from any other artificial source.

(Paragraphs 203–206.)

340. Watches and clocks with radioactively luminous dials contribute about one per cent of additional radiation. X-rays from television sets account for much less than one per cent. The contribution from X-ray apparatus used in shoe-fitting is not likely to exceed 0·1 per cent. (Paragraphs 207–210.)

341. The contribution arising from the work of the Atomic Energy Authority is the most accurately known, and is about 0·1 per cent. A study of the records of the National Radiological Protection Service has put the contribution from other occupational sources at about 1·6 per cent.

(Paragraphs 212–217.)

Contamination of the world by fall-out from the explosion of nuclear weapons

342. Continual watch is kept by the Atomic Energy Authority on the radioactive fall-out reaching this country from nuclear devices exploded in other parts of the world. From the bombs exploded up to the present time, the population of this country may expect to receive, over the next fifty years, additional radiation amounting to between 0·02 per cent and 0·04 per cent of the radiation which will be received over the same period from natural sources. (Paragraphs 218–229.)

343. If the firing of bombs were to continue indefinitely at the same rate as over the past few years, radioactivity would gradually accumulate to a level at which an inhabitant of this country would receive an average dose of 0·026 r over a period of thirty years, or about one per cent of that which he would receive in the same period from natural sources.

(Paragraph 230.)

344. The contribution to this figure from thermonuclear explosions, relative to their numbers, is very great. If the rate of firing of weapons of this type increases, exposure to radiation will be significantly raised. (Paragraph 231.)

Special hazards of radioactive fission products

345. It is unlikely that the inhalation of radioactive particles present in the air as a result of fall-out would constitute a problem in ordinary civil life. (Paragraphs 232.)

346. The deposition of radioactive strontium is probably a greater hazard, because it is soluble and, if ingested, is deposited and retained in bone. Measurements which have been made of radioactive strontium in bone show that the highest levels are at present about a thousand times less than is considered permissible for those who are occupationally exposed.

(Paragraphs 234–239.)

Atomic war

347. Atomic bombs were developed for their capacity to create blast, but for persons exposed in the open the heat flash is equally to be feared. The ionizing radiations produced immediately after explosions have a much greater penetrating power than the heat rays, but the range at which they cause death or immediate injury is somewhat less. The hazard from radiations is therefore only one of the immediate effects of atomic explosions. Their peculiar danger lies in their distant and delayed effects.

(Paragraphs 241–246.)

ASSESSMENT OF THE HAZARDS OF EXPOSURE TO RADIATION

348. An attempt is made to assess the medical and genetic consequences of exposure to radiation at the levels of dosage which occur now or which might conceivably come about. The naturally occurring level of radiation can be accepted as a standard of reference, because it is a level to which mankind has long been adjusted. (Paragraphs 247–248.)

349. In considering the genetic effects of radiation, we are concerned with the sum, over the whole population, of the total gonad dose received by its members from conception until the end of reproductive life. (Paragraphs 249–250.)

350. In considering the effects of radiation upon the individual, we are concerned with his whole span of life, and with the rate at which the radiation is received as well as with its total dosage; and we must have regard to the possibility that the severity of the effects produced by radiation may increase in more than equal proportion to the dosage that is received. (Paragraph 251.)

Dosage and effects on the individual

351. The acute effects of radiation which appear within two months of exposure to a single dose or a few heavy doses do not enter into ordinary civil calculations; nor is it feared that they may be produced by repeated exposures to doses that do not exceed 0·3 r per week. (Paragraphs 252–253.)

352. Of the delayed effects of irradiation of the whole body, leukaemia is probably the most easily induced. We consider that an individual could, without feeling undue concern about developing any of the delayed effects, accept a total dose of 200 r in his life-time, additional to that received from the natural background, provided that this dose is distributed over tens of years and that the maximum weekly exposure, averaged over any period of 13 consecutive weeks, does not exceed 0·3 r. We recommend, however, that the aim should always be to keep the level of exposure as low as possible. (Paragraphs 254–255.)

Dosage and genetic effects

353. The genetic effects of radiation are essentially problems concerning the future welfare of the population as a whole. (Paragraph 257.)

354. It follows from the nature of the genetic effects of radiation that a small fraction of a population can, without harm to its members, receive dosages of radiation which would be likely to have serious genetic effects if applied to the population as a whole. We feel that an individual, considered as such, can accept a total gonad dose of not more than 50 r, from conception until the age of thirty, additional to that received from the natural background, without undue concern for himself or his offspring, but that the number of such individuals should not exceed one-fiftieth of the population as a whole. (Paragraphs 258–262.)

355. Our present knowledge does not justify us in naming any specific figure as a limit for the average dose of radiation which might be received by the population as a whole. It is highly desirable that such a figure should be named as soon as possible; and we understand that the International Commission on Radiological Protection has this matter under consideration. In the meantime, we feel bound to state our opinion that it is unlikely that any authoritative recommendation will name a figure for permissible radiation dose to the whole population, additional to that received from the natural background, which is more than twice that of the general value for natural background radiation. The recommended value may, indeed, be appreciably lower than this. (Paragraph 263.)

The peacetime hazards from nuclear radiation

356. Nuclear energy may become the principal source of power. So far as its use affects the small numbers likely to be employed in its production, we believe that nuclear energy might make power available at a lower cost in accidents, illnesses and disability than that incurred in connexion with other sources of power. What is novel in the use of nuclear energy and the other, increasing, uses of processes producing radiations is the genetic risk to the community as a whole. The risk from civil usage is at present small, and seems unlikely ever to be large; but from the point of view of population genetics all possible extra radiation should be avoided, and it is not now too early to suggest where we might restrain its use. (Paragraphs 265–266.)

357. With regard to occupational exposure we consider that the record of the Atomic Energy Authority shows the standard that is attainable and the practicability of being satisfied with nothing less. (Paragraphs 270–276.)

358. We consider that the time has come for a review of present practice in diagnostic radiology, and of certain uses of radiation in the treatment of non-malignant conditions, particularly in children. Among the less important sources of radiation, we hope that the use of X-rays in shoe-fitting will be abandoned except when prescribed for orthopaedic reasons; that watches and clocks with radioactively luminous dials will be confined to necessary uses; and that the X-ray hazard from television tubes, at present negligible, will be borne in mind if special types of high voltage equipment come to be widely used. (Paragraph 267–269 and 277–279.)

Test explosions of nuclear weapons

359. The genetic effects to be expected from present or future radioactive fall-out from bombs fired at the present rate and in the present proportion of the different kinds are insignificant. They might not be so, if present rates of firing were increased and particularly if a greater number of thermonuclear weapons were tested. (Paragraph 280.)

360. So far as radioactive fall-out may affect the individual, we believe that immediate consideration would be required if the concentration of radioactive strontium in bone showed signs of rising greatly beyond that corresponding to one-hundredth of the maximum permissible occupational level. (Paragraphs 281–284.)

Wartime hazards

361. The area in which a greater or lesser proportion of those exposed would be at serious risk from the radioactivity released by the ground burst of a thermonuclear weapon is measured in thousands of square miles. If a sufficient number of nuclear weapons were exploded, no part of the world would escape biologically significant degrees of exposure or the load of distress and suffering to individuals and society which such exposure would entail. (Paragraphs 286–290.)

93299 O—57—pt. 2——40

CHAPTER VIII

CONCLUSIONS

362. On the basis of the considerations in this report we feel justified in drawing the following conclusions in relation to the use of ionizing radiations in peacetime :

1. *Limitation of the use of all sources of radiation*

Adequate justification should be required for the employment of any source of ionizing radiation on however small a scale.

2. *Dose levels to the individual*

(*a*) In conditions involving persistent exposure to ionizing radiations, the present standard, recommended by the International Commission on Radiological Protection, that the dose received shall not exceed 0·3 r weekly, averaged over any period of 13 consecutive weeks, should, for the present, continue to be accepted.

(*b*) During his whole lifetime, an individual should not be allowed to accumulate more than 200 r of "*whole-body*" radiation, in addition to that received from the natural background, and this allowance should be spread over tens of years; but every endeavour should be made to keep the level of exposure as low as possible.

(*c*) An individual should not be allowed to accumulate more than 50 r of radiation *to the gonads,* in addition to that received from the natural background, from conception to the age of 30 years; and this allowance should not apply to more than one-fiftieth of the total population of this country.

3. *Dose level to the population*

Those responsible for authorising the development and use of sources of ionizing radiation should be advised that the upper limit, which future knowledge may set to the total dose of extra radiation which may be received by the population as a whole, is not likely to be more than twice the dose which is already received from the natural background; the recommended figure may indeed be appreciably lower than this.

4. *Fall-out from test explosions of nuclear weapons*

(*a*) The present and foreseeable hazards from *external* radiation due to fall-out from the test explosions of nuclear weapons, fired at the present rate and in the present proportion of the different kinds, are negligible.

(*b*) Account must be taken, however, of the *internal* radiation from the radioactive strontium which is beginning to accumulate in bone. At its present level, no detectable increase in the incidence of ill-effects is to be expected. Nevertheless, recognising all the inadequacy of our present knowledge, we cannot ignore the possibility that, if the rate of firing increases and particularly if greater numbers of thermonuclear weapons are used, we could within the life-time of some now living, be approaching levels at which ill-effects might be produced in a small number of the population.

5. *Recommendations regarding specific uses of radiation*

(*a*) All sources of radiation, both medical and industrial, should be under close inspection, in order to ensure that the high standards of protection now

attainable against the absorption of ionizing radiations, and against radioactive materials, are generally observed. Those using radiations should be instructed in the precautions to be taken, and no unnecessary or unauthorised person should be allowed to engage in such occupations. A personal record, not only of doses of radiation received during occupation but also of exposures from all other sources, such as medical diagnostic radiology, should be kept for all persons whose occupation exposes them to additional sources of radiation.

(*b*) Present practice in medical diagnostic radiology should be reviewed, with the object of clarifying the indications for the different special types of examination now being carried out and defining more closely, both in relation to the patient and to the operators, the conditions which should be observed in their performance.

(*c*) The uses of radiotherapy in non-malignant conditions should be critically examined.

(*d*) The small amounts of irradiation from miscellaneous sources, such as X-ray machines used for shoe-fitting, luminous watches and clocks, and television apparatus, should be reduced as far as possible.

6. *Collection of vital statistics*

As an essential basis for future studies of the genetic effects of radiation, further data are required on the genetic structure of human populations; to this end, there is an urgent need for the collection of more detailed information, when births, marriages and deaths are registered.

ACKNOWLEDGEMENTS

We have expressed in our introductory chapter our sense of indebtedness to those who have been intimately concerned with the preparation of this report. We wish also to thank those others who have undertaken the preparation of special papers for the information of the committee, namely: Dr. J. D. Abbatt, Dr. W. Anderson, Dr. P. Armitage, Dr. Charlotte Auerbach, Mr. W. Binks, Mr. D. V. Booker, Dr. F. J. Bryant, Dr. R. A. M. Case, Mr. R. C. Chadwick, Mr. A. C. Chamberlain, Mr. R. N. Crooks, Dr. R. Doll, Miss E. M. R. Fisher, Dr. A. Glücksmann, Dr. A. W. G. Goolden, Professor J. B. S. Haldane, Dr. G. E. Harrison, Dr. W. G. Marley, Dr. R. H. Mole, Mr. A. Morgan, Mr. S. B. Osborn, Dr. Alan Robertson, Mr. E. E. Smith, Professor D. W. Smithers, Professor F. W. Spiers, Mr. R. W. Stanford, Mr. N. G. Stewart and Dr. R. C. Turner.

We have had the invaluable assistance of the following who have prepared appendices to the report: Dr. W. G. Marley, Mr. S. B. Osborn, Mr. E. E. Smith and Professor F. W. Spiers. We wish also to thank Miss Annette Todd, of the Council's Headquarters Staff, for her work in editing the appendices.

We feel a special debt of gratitude to the United States Atomic Bomb Casualty Commission and to Professor J. V. Neel and Dr. W. J. Schull, who have so kindly made available to us the data on the effects of exposure to the atomic bombs at Hiroshima and Nagasaki.

We wish to acknowledge the great help given to us by the staffs of a number of research departments in different hospitals and elsewhere, especially by Dr. W. G. Marley and the staff of the Health Physics Division of the Atomic Energy Research Establishment, Harwell, by members of the Department of Physics of the Institute of Cancer Research, Royal Cancer Hospital, London, of the Galton Laboratory, University College, London, of the Medical Research Council's Statistical Research Unit, London School of Hygiene and Tropical Medicine, London, and of the National Institute for Medical Research, London.

In connexion with certain statistical aspects of our work, our thanks are due to the Registrar General for England and Wales and to the Department of Health for Scotland.

We are grateful to those who assisted in the special investigation on the incidence of leukaemia among patients treated with X-rays for ankylosing spondylitis, especially to the following: Dr. J. D. Abbatt, Dr. F. Ellis, Dr. Joan Faulkner, Mr. D. Hewitt, Dr. A. J. Lea, Dr. J. H. Mulvey, Dr. W. D. Rider, Dr. A. Stewart, Dr. J. Stubbe and Dr. J. W. Webb, who were members of the teams which visited the radiotherapy centres; to the staffs of the 70 centres in England, 3 in Wales and 9 in Scotland, who freely gave their help in the compilation of the case records for this study; to the Registrars General for England and Wales, Scotland and Northern Ireland, the Deputy Registrar General for the Isle of Man, the Superintendent Registrar, Jersey, Channel Islands, and Her Majesty's Greffier for Guernsey and Dependencies, who provided valuable information; to the Ministry of Pensions and National Insurance, who made their records available and gave much help, and to Dr. J. D. Abbatt and Dr. A. J. Lea who made a special study of these records; to Dr. J. V. Dacie and Dr. I. Doniach who undertook to review

pathological material; to Dr. F. Campbell Golding and Mr. H. J. Seddon who gave expert help and advice; to Mr. R. Ellis, Dr. D. G. Jones, Mr. D. E. A. Jones, Mr. W. C. Lister, Dr. R. J. Munson, Miss J. Perrett, and Dr. B. M. Wheatley, who carried out much arduous work in connexion with dose measurements; and more especially to Dr. W. M. Court Brown and Dr. R. Doll, who were responsible not only for planning the investigation and the compilation of the results, but who also carried out many of the visits and undertook much of the detailed preliminary work themselves.

We wish to record our appreciation of the work of Mr. S. B. Osborn in connexion with his study on the contribution made by diagnostic radiology to the present level of ionizing radiation in this country. We are grateful to the following bodies who co-operated in the study: the Ministry of Health, the Royal Navy, the Royal Army Medical Corps, the Royal Air Force, the Medical Research Council's Pneumoconiosis Research Unit, the National Coal Board, the Ministry of Pensions and National Insurance, the Ministry of Supply, the Ministry of Labour and National Service, the Atomic Energy Research Establishment and the Red Cross and St. John Joint Committee. Our thanks are also due to those hospitals which supplied detailed data on diagnostic X-ray examinations carried out by them.

A number of commercial firms provided information for the study on radiation dose levels in this country. In this connexion we are particularly grateful to the following: members of the British Radio Valve Manufacturers' Association, Brandhurst Co. Ltd., L. Newmark Ltd., Reliance (Nameplates) Ltd., Smiths English Clocks Ltd., Timex Watches, and the Pedoscope Co. Ltd. Other bodies also provided information and especially the British Dental Association, the London Chamber of Commerce, the Horological Institute of Great Britain, the National Physical Laboratory, the Ministry of Transport and Civil Aviation and the Ministry of Labour and National Service.

Finally, we wish to thank all those who have advised us on specialist problems from time to time during our work, especially Sir Stewart Duke-Elder, Professor Aubrey Lewis and Professor Arnold Sorsby, for the help that they have given.

APPENDIX A

The Incidence of Leukaemia among the Survivors of the Atomic Bomb Explosions at Hiroshima and Nagasaki

Information concerning the cases of leukaemia which are known to have occurred among the survivors of the atomic bomb explosions at Hiroshima and Nagasaki has been supplied by the Atomic Bomb Casualty Commission of the National Research Council of the U.S.A. By the end of August 1955, the diagnosis of leukaemia had been confirmed in 125 patients; in all these cases blood smears and, when necessary, bone-marrow and autopsy material, had been examined by a member of the Commission's staff. In 18 other cases, the diagnosis was suspected but the evidence was less conclusive; and in a further 5 the diagnosis was still under review.

Sixty-one of the confirmed and four of the suspected cases occurred among persons resident in Hiroshima at the time the diagnosis was made, and it is possible to relate these cases to the numbers of persons who survived the explosion and who were recorded as residing in the city subsequently. The incidence of leukaemia among survivors at various distances from the hypocentre of the explosion is shown in Table 1A. The incidence was substantially higher among those who were close to the hypocentre than among those who were more distant from it—128·0 per 10,000 among those less than 1,000 metres away, against 1·6 per 10,000 among those more than 3,000 metres away. Separate incidence rates for persons at each distance who showed major radiation symptoms shortly after the explosion and for persons who did not show such symptoms have been published by Moloney and Kastenbaum (1955).

TABLE 1A

The incidence of leukaemia among survivors of the Hiroshima atomic bomb explosion exposed at various distances from the hypocentre; persons subsequently resident in Hiroshima City only

Distance from hypocentre at time of explosion (m.)	No. of survivors on 1.10.50*	No. of cases of leukaemia		Incidence per 10,000 persons (total cases)
		Confirmed	Suspected	
Less than 1,000 ...	1,250	16	0	128·0
1,000–1,499	10,350	28	1	28·0
1,500–1,999	18,450	6	1	3·8
2,000–2,999	30,350	7	0	2·3
3,000 or more	37,700	4	2	1·6
All distances	98,100	61	4	6·6

* The numbers of survivors have been rounded off to the nearest 50. The estimates differ slightly from those published by Moloney and Kastenbaum (1955) in accordance with data provided by the Atomic Bomb Casualty Commission.

Comparable figures are not available for the incidence of leukaemia in the unexposed population of the rest of Japan, but since leukaemia is invariably fatal it is reasonable to use mortality figures to provide an estimate of the incidence of the disease which might have been expected if no explosion had

taken place. National mortality figures are, however, based on the causes of death given on death certificates, and they are not necessarily suitable for comparison with figures obtained after an intensive search for cases and after the submission of each case to expert clinical scrutiny. In fact, the use of national mortality data is justified only by the fact that the number of deaths attributed to leukaemia among survivors who were 2,000 metres or more from the hypocentre and who cannot have received more than very small amounts of radiation, is close to the expected number calculated on the basis of these data. Table 2A therefore presents for comparison the numbers of cases of leukaemia known to have occurred during the eight years from 1947 to 1954 among residents of Hiroshima who survived at different distances from the hypocentre, and the numbers of deaths from leukaemia which would have been expected in a similar period among populations of the same size and the same sex- and age-distribution, subjected to the age- and sex-specific mortality rates from leukaemia observed in the whole of Japan in 1952. It can be seen that the observed incidence among survivors who were less than 1,000 metres from the hypocentre is 100 times greater than the mortality which would have been expected.

TABLE 2A

A comparison between the observed and the expected incidence of leukaemia among survivors of the Hiroshima atomic bomb explosion exposed at various distances from the hypocentre; persons subsequently resident in Hiroshima City only

Distance from hypocentre at time of explosion (m.)	No. of cases with onset in the 8-year period 1947–54		No. of deaths expected among the survivors in an 8-year period*	Ratio of total cases observed to expected
	Confirmed	Suspected		
Less than 1,000 ...	15	0	0·15	100·0 : 1
1,000–1,499	28	1	1·32	22·0 : 1
1,500–1,999	6	1	2·33	2·6 : 1
2,000–2,999	6	0	3·96	1·5 : 1
3,000 or more	4	2	4·83	1·2 : 1
All distances	59†	4	12·59	4·7 : 1

* Calculated from the Japanese mortality data for 1952. In calculating the numbers of expected deaths, certain assumptions had to be made about the rate of change of the numbers of survivors in the different age groups, and the figures must be regarded as approximate estimates.

† Two cases referred to in Table 1A are omitted, since the onset of symptoms in one patient was in 1955 and in another patient, who died in April 1955, the date of onset is unknown; the latter patient was exposed at a distance of 2,400 metres from the hypocentre.

The data available for survivors of the Nagasaki explosion are less detailed than those for survivors of the Hiroshima explosion. Altogether 32 confirmed cases and 11 suspected cases are known to have occurred among survivors who subsequently resided in Nagasaki. Of these, 32 and 10 respectively occurred during the eight years 1947-54, and the corresponding total number of deaths which might have been expected in that period on the basis of the national mortality data is approximately 12·3.

Table 3A shows the year of onset of the disease for each of the 108 cases which have occurred among the survivors resident post-war in Hiroshima or Nagasaki, together with estimates of the annual incidence rates. The rates in

the first two years may be under-estimated, since medical organisation was incomplete at that period; in 1953 and 1954 they are almost certainly under-estimated since new cases continue to be discovered and some of the patients give histories of one or more years' duration. The data provide no evidence of a sharp peak in incidence at any particular period after the explosion, nor any clear indication that the incidence has yet begun to diminish by the end of the ninth year.

TABLE 3A

The incidence of leukaemia in different years among survivors of the Hiroshima and Nagasaki atomic bomb explosions; persons subsequently resident in Hiroshima City and Nagasaki only

Year of onset	No. of cases at Hiroshima		No. of cases at Nagasaki		Incidence per 10,000 persons (total cases)		
	Confirmed	Suspected	Confirmed	Suspected	Hiroshima	Nagasaki	Hiroshima and Nagasaki
1946 ...	0	0	0	1	0·0	0·1	0·05
1947 ...	3	0	2	0	0·3	0·2	0·3
1948 ...	7	3	2	1	1·0	0·3	0·7
1949 ...	5	0	1	2	0·5	0·3	0·4
1950 ...	6	1	5	1	0·7	0·6	0·7

APPENDIX B

Leukaemia and Aplastic Anaemia in Patients Treated with X-rays for Ankylosing Spondylitis

(A summary of the findings of the investigation sponsored by the Medical Research Council Committee reporting on the hazards to man of nuclear and allied radiations)

The investigation had two main objectives: first, to see whether the incidence of leukaemia and of aplastic anaemia was abnormally high in patients treated with X-rays for ankylosing spondylitis; and second, if the incidence of those conditions was found to be raised, to determine the quantitative relationship between incidence and dose of X-rays.

RESULTS

The incidence of leukaemia and aplastic anaemia

The case records of 13,352 patients (11,287 men and 2,065 women) were studied; these patients had been treated at 81 radiotherapy centres and sub-centres during the period 1935–54 inclusive. Slightly fewer than half of them were known to have been alive in 1955 or to have died earlier; the remainder were lost to follow-up at various dates between 1935 and 1954. They had therefore been under observation for periods of between one and twenty years, with an average for the whole group of just under five years.

49 of the patients studied were found to have developed leukaemia, aplastic anaemia, or myelofibrosis (a condition considered to be possibly a variant of leukaemia), and, of these, 46 had died by the end of 1955; 28 of them were certified as having died from leukaemia, 13 from aplastic anaemia and 1 from myelofibrosis. Three other patients with leukaemia and 1 with aplastic anaemia were found, who had been certified as having died from other causes.

With the co-operation of the Registrars-General, special efforts were made to recognise all patients in the series who had died of leukaemia or aplastic anaemia. The great majority of such cases have probably been traced despite the incomplete follow-up, but there is reason to believe that a few more might be revealed if the follow-up could be made complete.

The numbers of deaths from leukaemia and aplastic anaemia which could be expected under normal conditions were calculated from the national death rates for those diseases in the general population: they have been estimated as 2·9 and 0·3 respectively up to the end of 1955, but these estimates are certainly too high, as they are based on the assumption that all the patients untraced in 1955 were, in fact, alive at the end of 1955. In the compilation of the numbers of observed deaths from leukaemia and aplastic anaemia for comparison with these figures, only deaths *certified* as due to these conditions could be used, since the figures for expected deaths are based on death-certificate data. Thus enumerated, the numbers of observed deaths from leukaemia and aplastic anaemia are respectively 28 and 13. The differences between the observed and expected deaths are highly significant for both diseases.

Three of the observed cases of leukaemia died within the first year, and in these cases it was assumed that leukaemia was already present at the time of first treatment. If these 'co-existent' cases, and the corresponding expected mortality in the first year after treatment, are omitted, the observed and expected numbers of deaths from leukaemia for 1935–55 are 25 and 2·4 respectively.

Clinical review of cases

All the relevant data for each case were reviewed, and it was concluded that many of the patients certified as having died of aplastic anaemia had, in fact, been suffering from aleukaemic leukaemia. The diagnosis of aplastic anaemia was substantiated in only 4 cases and it was, therefore, not possible to examine the relationship between the incidence of this condition and the dose of X-rays received.

The relationship between the incidence of leukaemia and the X-ray dose

This relationship has been determined for male patients only, in order to avoid difficulties introduced by the possibility of there being a sex-difference in susceptibility to leukaemia; the 3 'co-existent' cases were excluded, and there then remained 37 cases of leukaemia for study.

Details of X-ray treatment were obtained from the case records for 1,878 men, a sample of approximately 1 in 6 of the whole group of 11,287 male patients. The X-ray dose was expressed in two ways. By the first method, the total energy absorbed in the whole body was calculated, and expressed in megagramme-roentgens (Mgm.r.); by the second, the maximum dose in the spinal marrow was determined and expressed in roentgens (r)*. The number of man-years at risk following each level of dose, calculated by each of the two methods, was estimated for the whole group of male patients and was related to the number of cases of leukaemia. The results of these calculations are given in Tables 1B and 2B, which show the crude incidence rates per 10,000 men per year at all levels of dose.

TABLE 1B

The numbers of male patients developing leukaemia and the crude incidence rates after different doses of radiation (measured by the total amount of energy absorbed by the whole body)

	Amount of treatment: whole-body integral dose (Mgm.r.)						
	0	Less than 7·5	7·5–14·9	15–22·4	22·5–37·4	37·5–52·4	52·5 or more
Number of men developing leukaemia ...	—	1	9	9	10	4	4
Crude incidence per 10,000 men per year ...	0·5†	0·7	4·7	5·1	11·3	22·6	60·2

* For the second method extensive measurements were made on a 'phantom' man.

† The rate given for 'no treatment' has been estimated from the national vital statistics for all forms of leukaemia, and weighted to allow for the fact that not all the patients in the series were certified as dying from leukaemia. If lymphatic leukaemia is excluded (as may be more appropriate) the rate is 0·3.

TABLE 2B

The numbers of male patients developing leukaemia and the crude incidence rates after different doses of radiation (measured by the maximum amount received at a point in the spinal marrow)

	Amount of treatment: maximum dose to the spinal marrow (r)						
	0	Less than 500	500 to 999	1,000 to 1,499	1,500 to 1,999	2,000 to 2,749	2,750 or more
Number of men developing leukaemia ...	—	2	8	8	8	6	5
Crude incidence per 10,000 men per year ...	0·5*	2·2	4·1	4·2	11·3	13·0	17·6

* The rate given for 'no treatment' has been estimated from the national vital statistics for all forms of leukaemia, and weighted to allow for the fact that not all the patients in the series were certified as dying from leukaemia. If lymphatic leukaemia is excluded (as may be more appropriate) the rate is 0·3.

CONCLUSIONS

Deaths from leukaemia have been found to be greatly increased among the patients studied, and it is believed that this increase is the result of exposure to X-rays; the possibility that sufferers from ankylosing spondylitis are unusually sensitive to the action of X-rays cannot, however, be excluded.

Both methods of estimating the dose show a relationship between the crude incidence of leukaemia and the dose of X-rays, with an increase in the incidence over the whole range of dose studied. With neither method is there any evidence of a threshold below which no increase in incidence is produced. Both sets of results, therefore, suggest that even very small amounts of radiation will have an appreciable effect if given to a large enough population. The method based on calculation of the whole-body energy absorption, however, shows a disproportionately greater increase at high levels of dose, whereas that based on calculation of the spinal-marrow dose shows a simple proportional increase at all levels of dose. It is of considerable importance to determine the reason for this discrepancy. If the true relationship is of the curvilinear type suggested by the first method, it remains a theoretical possibility that very small doses (which could not be tested in the investigation) will have no leukaemogenic effect at all; but such a possibility can almost be ruled out if the relationship is linear.

A full account of the investigation will be published by H.M. Stationery Office as a report in the Medical Research Council's Special Report Series.

APPENDIX C

The Spontaneous Mutation Rate in Man

In certain circumstances the spontaneous mutation rate of human genes, expressed as the number of mutations per locus per generation, can be estimated with a fair degree of reliability. A direct count of cases due to fresh mutation can be made for a gene which has a dominant effect. This number can also be directly inferred for sex-linked traits shown only in the male. If the incidence of a trait in the general population is known, the mutation rate can be determined from the proportion of cases due to fresh mutation.

When the effects of a gene are very disadvantageous a different line of argument can be used, even though the gene may not be fully manifest in the heterozygous state. The principles on which the indirect estimation of mutation rates can be made were laid down by Haldane (1932), and they are used in the formulae given in Appendix D. The assumption is made that the human population is in a state approaching genetical equilibrium; it is supposed that disadvantageous genes could not have persisted in the population unless their extinction by selective mortality were balanced by the recurrence of mutation.

In the case of dominant or sex-linked characters associated with very high mortality, the direct measurement of mutation rate can be supplemented by the indirect argument. Estimates which are entirely indirect are untrustworthy, but they have been made for a variety of genes recognised only by their recessive effects. One difficulty with recessive traits is that allowance has to be made for the effects of inbreeding. Another likely source of error is that genetical equilibrium can be maintained not only by mutation but also by a slightly advantageous effect in the heterozygote. Hence, indirect estimates are likely to be too high.

There is a further general difficulty; this arises from uncertainty as to whether or not a single locus is involved in determining the trait under consideration. Mutations at two or three loci might produce similar characters; this apparently occurs in haemophilia and also in achondroplasia. In these circumstances any estimate of mutation frequency, direct or indirect, based upon accepting one locus as the hereditary cause of the trait, would be too high by a factor depending upon the frequencies of the component causal genes.

Estimates of mutation rate in man are given in Table 1C. Those for dominant traits are based upon the direct method, though they can all be indirectly supported; the estimates for sex-linked genes are calculated indirectly, but are supported by direct observation of pedigrees almost certainly containing freshly mutated genes; those for recessive traits are all indirectly estimated.

I should like to acknowledge here the assistance given me in connection with Appendices C, D, and E by Dr. H. Harris and Dr. D. A. Sprott.

APPENDIX D

Calculation of the Quantitative Effects of Spontaneous and Induced Mutation Rates in Diseases Caused by Single Genes

In order to estimate the quantitative effect of doubling the mutation rate or of raising it by any given factor, it is necessary to calculate the proportion of cases of the disease in question in each generation which can be attributed to spontaneous mutation. This can be done by using the indirect method of calculating mutation rate; the steps in the argument are set out in Table 1D. The abnormal allele is represented by **a**, and the normal by **A**.

TABLE 1D

Calculation of the number of cases due to spontaneous mutation in diseases caused by single genes

Steps in the calculation	Dominant trait: Formula	Dominant trait: Example: achondroplasia	Sex-linked trait: Formula	Sex-linked trait: Example: haemophilia	Recessive trait: Formula	Recessive trait: Example: phenylketonuria
1. Sex affected ♂ or ♀	♂ or ♀	—	♂	—	♂ or ♀	—
2. Genotype responsible for the disease	Aa	—	a	—	aa	—
3. Frequency of genotype in population (where q is the frequency of a)...x	2q	1/10,000	q	1/12,000	q^2	1/40,000
4. Comparative loss of fitness associated with the genotype	(1–F)	4/5	(1–F)	7/8	(1–F)	1
5. Mutation rate of A to a per gene per generation ......m	q (1–F)	40×10^{-6}	q (1–F)/3	24×10^{-6}	q^2 (1–F)	25×10^{-6}
6. Proportion of genotypes (or cases of the disease) due to fresh mutation in each generation .... d	(1–F)	4/5	(1–F)/3	7/24	2q (1–F)	1/100
7. Frequency of abnormal genotypes due to fresh mutation:— (i) in each generation of births .... x × d	2m	80×10^{-6}	m	24×10^{-6}	2mq	$0{\cdot}25 \times 10^{-6}$
(ii) among 20×10^6 births (♂ and ♀) over a period of 30 years ...	$40m \times 10^6$	1,600	$10m \times 10^6$	240	$40mq \times 10^6$	5

In this table three hereditary diseases, achondroplasia, haemophilia and phenylketonuria are used to show the methods applicable respectively to dominant, sex-linked and recessive traits determined by single genes. For the present purpose the population is assumed to be in genetical equilibrium; the loss due to unfitness of genotypes is balanced by recurrent natural mutation. The figures for achondroplasia are derived from Mørch (1941); in Step 3, 1/9,400 has been rounded off to 1/10,000. For haemophilia the figure (7/8) in Step 4 has been taken from Andreassen (1943) and that in Step 3, (1/12,000), agrees with estimates by Haldane (1935). The figures in Steps 3 and 4 for phenylketonuria are derived from Jervis (1939) and Munro (1947). Doubling the spontaneous mutation rate on one occasion would increase the frequency of each disease by a proportion, shown in Step 6, in the next generation.

The results given in Step 7 (ii) in Table 1D apply only to the first generation after doubling. The quantitative effects in subsequent generations can be ascertained by substituting appropriate new incidence figures and repeating the steps of the calculation. Calculations made by this method and extended to cover six generations yield the results shown in Table 2D; the theoretical limiting values obtained after an infinite number of generations are also given. The results are shown graphically in Fig. 1 (p. 32). Two situations are considered: (*a*) the effect of a single doubling of mutation rates in one generation, and (*b*) the effect of permanently doubling the mutation rate.

TABLE 2D

The effects, expressed as the increase in incidence per hundred cases, of doubling the mutation rates, (a) *in one generation only, and* (b) *permanently, for three hereditary traits*

(*a*) *Doubling in one generation only*

Number of generations	Increase in incidence per hundred cases		
	Achondroplasia (Dominant)	Haemophilia (Sex-linked)	Phenylketonuria (Recessive)
0	0	0	0
1	80	29	1
2	16	29	1
3	3	16	1
4	1	10	1
5	0	6	1
6	0	4	1
Infinite	0	0	0

(b) Permanent doubling

Number of generations	Increase in incidence per hundred cases		
	Achondroplasia (Dominant)	Haemophilia (Sex-linked)	Phenylketonuria (Recessive)
0	0	0	0
1	80	29	1
2	96	58	2
3	99	74	3
4	100	84	4
5	100	90	5
6	100	94	6
Infinite	100	100	100

APPENDIX E

Estimate of the Incidence of Cases of Schizophrenia and Manic Depressive Reaction due to Spontaneous Mutation

The calculation of (d), the proportion of cases which can be attributed to fresh mutation in each generation, for the conditions discussed in paragraphs 148–150, can be set out as shown in Table 1E.

TABLE 1E

Calculation of (d), *the proportion of cases due to fresh mutation in each generation, in schizophrenia and manic depressive reaction*

Steps in the calculation	(i) Schizophrenia		(ii) Manic depressive reaction	
	Formula	Example	Formula	Example
1. Sex affected ♂ or ♀	♂ or ♀	—	♂ or ♀	—
2. Genotype responsible for predisposition to the disease ...	aa	—	Aa	—
3. Frequency of genotype in population (where q is the frequency of a) x	q^2	1/100	2q	1/200
4. Comparative loss of fitness associated with the genotype ...	(1–F)	1/20	(1–F)	1/70
5. Mutation rate per gene per generation ... ... m	q^2 (1–F)	1/2,000	q (1–F)	1/28,000
6. Proportion of predisposed cases due to fresh mutation in each generation ... ... d	2q (1–F)	1/100	(1–F)	1/70

(*i*) *Schizophrenia*

This is a type of mental disease which has its onset at about the age of 30 years on the average. There are many degrees of severity, and males are more often affected than females. The genetical predisposition occurs in subjects who are, according to Kallmann (1938), homozygous for a specific recessive gene; it has an incidence of about 1/100 in European populations (Fremming, 1947). On the basis of a rough survey of hospital data, it is assumed here that only one-tenth of predisposed subjects become chronically incapacitated. Neglecting sex differences, the fertility of these incapacitated patients is reduced by 1/2 (Essen-Möller, 1935). The total loss of fitness of predisposed genotypes is thus 1/10 × 1/2 = 1/20. It follows that d=2q(1–F)=1/100, as shown in Table 1E. In a generation of 20 × 10^6 births the number of incapacitated people would be 20,000, of whom 200 would be cases due to fresh mutation.

(ii) Manic depressive reaction

This is a type of mental disease with mean age of onset at about 40 years. There are many degrees of severity, and females are more often affected than males. The genetical predisposition, which is commonly believed to depend upon a dominant gene (Marrell, 1951), has a frequency in the population of about 1/200; Mayer-Gross, Slater and Roth (1954) quote 0·35 per cent for Scotland and 1 per cent for Sweden and Denmark as the total morbidity risk of affective psychosis. The incidence of chronic breakdown among those who are predisposed can be estimated at one-seventh and, for such incapacitated patients, fertility is reduced, according to observations by Essen-Möller, by a factor of 1/10. Hence the total loss of fitness for predisposed genotypes is $1/7 \times 1/10 = 1/70$. It follows that $d = (1-F) = 1/70$. In a generation of 20×10^6 births there would be 14,000 people incapacitated, of whom 200 would be cases due to fresh mutation.

APPENDIX F

The Effect of Changing the Mutation Rate on Characters Showing Continuous Variation about the Normal

Member genes of a polygenic system cannot be followed as individuals in our observations. We must therefore measure mutation by the increment it adds to heritable variation, instead of measuring it by the frequency of change, as is done in the case of individually traceable genes.

The increment added to the variance per generation has been estimated for spontaneous mutation in two hair characters in *Drosophila* (Clayton and Robertson, 1955; Durrant and Mather, 1954; Paxman, 1955). Technically this is a difficult operation, but the estimates agree surprisingly well for each character when allowance is made for various possible sources of bias. The two characters agree, also, in showing an increment of about 1×10^{-3} of the amount of heritable variation estimated by Clayton and Robertson to be present in a normal population of *Drosophila*. The estimate may easily be too small by a factor of 2 or 3, but seems unlikely to be out by a factor of 10. This finding suggests that the relation between the amount of heritable variation in a population and the mutation rate is roughly linear, and certain theoretical considerations point the same way. It also shows that a marked increase in the mutation rate for a few generations would have only a trivial effect on the heritable variation of the population, and that, even with a persistent increase, the new equilibrium showing the full effect of the raised mutation rate in raising heritable variation would take very many generations to achieve.

Clayton and Robertson also record the result of irradiating the adults of each generation with an X-ray dose of 1,800 r. The increment added in each generation to the heritable variation available to selection was about ten times the spontaneous increment. Thus the dose which doubles the effect of spontaneous mutation would be some 200 r as measured by this criterion. But the new heritable variation available to selection in these experiments seems to have represented only about one-sixth of all the new heritable variation as measured directly by the increase in phenotypic variation. If we take the overall total therefore, 200 r must have produced about six times the spontaneous increment, so that the doubling dose becomes just over 30 r. This is more in keeping with the figure obtained from lethal mutation, though it might have been expected that the polygenic figure would be higher, not lower, than the monogenic, because of the way in which mutations can balance one another's effects in a polygenic system. It would, in any case, be unwise to place great confidence in these calculations, both because other experiments of the same kind have given results even more difficult to assess, and because doses as heavy as 1,800 r produce so many lethal mutations and so much structural change in the chromosomes that the polygenic effects may well be quantitatively distorted.

In attempting to extrapolate from these findings to the effects of irradiation in natural, including human, populations, two points must be borne in mind. Firstly, the flies which yielded these observations were from inbred lines, so that any mutation in the polygenic system would add its quota to the increase in variation. In a natural population, however, variation is already present, and mutation from one allele to another, where both already exist

and are not uncommon in the population, could add little if anything to the variation. Only mutation in genes whose alleles are rare or absent in the population will contribute materially to an increase in variation, and the contribution will fall off as the alternative alleles become more common. So if most of the member genes of a polygenic system are already varying, mutation will add correspondingly little to the total variation. On the other hand, if, as seems likely, many of the genes which can prospectively contribute to the variation of a polygenic system are not doing so because only one allele is present or at least common, new mutation increases the number of loci contributing to the variation which will then increase correspondingly. The roughly linear relation between mutation and variation suggested by the experiments is thus to be regarded as a maximum effect, the closeness of approach to it depending on the initial conditions of variation prevailing in the population in question.

The second point concerns the properties of heterozygotes. The linear relation would cease to hold if there were any innate advantage of individuals heterozygous for the genes over others homozygous for them. A situation analogous to balanced polymorphism would then arise, and at equilibrium the heritable variation would become independent of mutation rate. No such heterozygotic advantage was detected in the variation arising by mutation, even though Paxman made a special search for it; nor is it likely on general grounds. Such an advantage must, however, remain as a possible, even if unlikely, additional reason for regarding a linear relation as representing the maximum, rather than the regularly realisable, effect of mutation on variation in populations such as those of man. In other words a permanent doubling of the mutation rate would not be expected to do more, and under some circumstances might do less, than double the heritable variation in the population.

APPENDIX G

The Effect on the Distribution of Intelligence of Increasing the Heritable Variation

Under conditions of natural selection the effect of raising the heritable, and hence the total, variation of expression of a character, some particular expression of which is the fittest, must in general be to lower the average fitness in the population; though where the mean departs widely from the most advantageous expression of the character the fitness of selected groups might be raised. Furthermore, where all expressions of the character may be displayed, the overall fall in fitness must be directly related to the increase in variation. A fall in fitness is not, however, to be translated directly into social load when we are considering the consequences of raising the heritable variation in such a character as mental capacity in man.

The intelligence score of an individual is derived from his performance in a series of tests, and the frequency distribution obtained from a population must therefore reflect the structure of the tests. The distribution obtained is generally treated as being normal, but in fact certain disturbances occasionally appear, and they seem to be of a type which no simple transformation or statistical adjustment can remove. It is very likely that such discrepancies spring from innate features of the test, and they should not, in any case, be allowed to obscure the essentially normal nature of the distribution. Normality will in fact be assumed in the following discussion. It is considered that by avoiding the use of very narrow ranges and, more particularly, by discusssing relative rather than absolute effects, broadly valid conclusions should be attained.

I am informed by Professor F. A. Peel of the Department of Education in the University of Birmingham, that in educational discussions the distribution of intelligence scores is taken as normal and is standardised to a mean of 100 with a standard deviation of 15. The scores have been found to approximate to I.Q.'s as measured by the original tests, and are commonly referred to as 'I.Q. scores'. In these terms, Professor Peel further informs me, children with an I.Q. of less than 70 are generally regarded as educationally sub-normal and as requiring education in special schools; those with an I.Q. of betwen 70 and 80 are regarded as needing special teaching in ordinary schools; and those with an I.Q. of over 115 as being of grammar school quality. These figures are to be taken only as general guides since they are applied neither rigorously nor uniformly throughout the country.

For information and advice on the estimation of the heritable variation in respect of I.Q., I am indebted to Dr. J. A. Fraser Roberts. Sibs show a correlation close to 0·5 in this character. Data on parent-offspring relations are less full, but suggest a similar figure, so that there is no good reason to postulate any over-dominance or heterozygous advantage. Taken on their face value, such figures would indicate virtually complete genetic determination, but there is strong assortative mating in respect of this character and there is also the effect of a common home environment to be taken into account in assessing the genetic meaning of these familial correlations. Observations on twins and foster children would seem to indicate $\frac{3}{4}$ as the fraction of variation which is heritable. However, lest this should be an over-estimate, parallel calculations have been made, assuming fractions of $\frac{1}{2}$ and $\frac{3}{4}$ as likely to straddle the true situation. Should even the figure of $\frac{1}{2}$ be too high the effect of increasing the heritable component would be correspondingly smaller. Assortative mating has been disregarded, as we may

reasonably assume that its incidence would not be affected by alteration in the amount of heritable variation, so that its relative effect would remain the same.

Calculations have been made of the effects of raising the heritable variation (V_H) to 1·25, 1·50 and 2·00 times its present value, assuming that environmental variation (V_E) remains unaltered. Thus, taking V_H to be $\frac{3}{4}$ of the total variation (V_T) we have:

$$V_H = \tfrac{3}{4}V_T = \tfrac{3}{4} \times 15^2, \text{ and}$$
$$V_E = V_T - V_H = \tfrac{1}{4} \times 15^2,$$

so that doubling the heritable variation would give us the new total:

$$V_T' = V_E + 2V_H = (\tfrac{1}{4} \times 15^2) + (2 \times \tfrac{3}{4} \times 15^2) = 1\tfrac{3}{4} \times 225 = 393{\cdot}75$$

and the new distribution of I.Q. would have a standard deviation of 19·84, the mean remaining at 100. The proportion of individuals expected to have, for example, an I.Q. of less than 70 can then be found as the area in the tail of the distribution cut off by the ordinate falling short of the mean by a normal deviate of $\frac{30}{19{\cdot}84} = 1{\cdot}512$.

The results of this and similar calculations are shown in Table 1G, where they are expressed as values relative to the proportion calculated as falling into corresponding classes with the distribution as it is now assumed to be. Thus the assumed present distribution ($\bar{x} = 100$, $s = 15$) gives 2·27 per cent of individuals with an I.Q. of less than 70. With the heritable fraction at $\frac{3}{4}$ of the total and doubled, 6·53 per cent fall below a score of 70, making a relative value of $\frac{6{\cdot}53}{2{\cdot}27} = 2{\cdot}88$. In other words, on these assumptions, doubling the heritable variation would nearly treble the number of children with an I.Q. of less than 70 (i.e. those needing to be taught in special schools, as judged by a common convention of today). In addition to the relative changes in the numbers with an I.Q. of less than 70, figures are also given for those in the classes with I.Q. less than 75 (a figure sometimes taken to indicate the need for special schooling), I.Q. between 70 and 80 (special teaching), and I.Q. over 115 (grammar school).

TABLE 1G

The effects of raising the heritable variation on the frequencies of different intelligence groups

Intelligence group	Present proportion per cent of population (assuming a normal distribution)	Assumed present heritable fraction	Factor of increase relative to present proportion with heritable variation raised to: (constant mean)			(falling mean)
			1·25	1·5	2·0	2·0
I.Q. < 70	2·27	$\frac{1}{2}$	1·31	1·62	2·26	3·24
		$\frac{3}{4}$	1·46	1·94	2·88	4·51
I.Q. < 75	4·78	$\frac{1}{2}$	1·22	1·42	1·82	2·50
		$\frac{3}{4}$	1·32	1·63	2·17	3·24
70<I.Q.<80	6·85	$\frac{1}{2}$	1·09	1·16	1·27	1·59
		$\frac{3}{4}$	1·13	1·22	1·33	1·75
I.Q.>115	15·87	$\frac{1}{2}$	1·09	1·17	1·30	1·00
		$\frac{3}{4}$	1·13	1·24	1·42	

In these calculations the variance has been assumed to change without alteration of the mean, so that the proportion of high I.Q. increases with the proportion of low I.Q. A further calculation has been made in which, as the variance increases, the mean is allowed to fall so as to keep constant the proportion with I.Q.'s of over 115. This is intended to illustrate the kind of result which would be obtained if mutation were preponderantly, but not wholly, degradatory. The relative changes for doubled heritable variation on this assumption are also shown in the table.

It should be remembered that these changed proportions would be achieved by corresponding increases in the mutation rate, only when equilibrium had been reached or at least closely approached, that is to say, after very many generations.

APPENDIX H

The Doubling Dose of Radiation for Various Plants and Animals

In paragraphs 171-182 we were concerned with finding some quantitative measure of the effectiveness of radiation in causing mutations, with the purpose of using this estimate to establish maximum levels of exposure which are genetically tolerable. In this context, one must be particularly careful not to under-estimate the effects of radiation. In order to express its influence in terms of a 'doubling dose', we should try to arrive at a figure for the lowest dose of radiation which changes mutation in a way which is effectively equivalent to a doubling of the mutation rates of every gene. For those genes with very low spontaneous mutation rates a doubling of the rate will be relatively unimportant. Among the genes with relatively greater spontaneous mutation rates, some may be more sensitive to radiation than others. What we need to estimate is the dose of radiation which doubles the mutation rate of a sample of these more sensitive genes sufficiently large to be physiologically representative of mutations in general. This might be called a 'minimum representative doubling dose'.

After pointing out (paragraph 176) that this can scarcely be less than the naturally occurring dose of radiation, we discuss the possible modifications of this bedrock minimum in terms of an argument which was originally largely due to J. B. S. Haldane (1948). This consists of an attempt to estimate the fraction of the spontaneous mutation rate in man which can plausibly be attributed to natural radiation. The argument proceeds by analogy with the conditions in other organisms, and particularly those in the fruit-fly (*Drosophila*) and the mouse.

In *Drosophila*, suppose that:

f = the fraction of spontaneous mutations due to natural radiation,

r = the rate of natural radiation (in r per day),

m = the rate of mutation induced by 1 r,

s = the spontaneous mutation rate,

t = the average age at reproduction (in days).

Then we shall have:

$$f = \frac{m\,r\,t}{s}$$

Similarly if capital letters represent the same factors in man, we shall have

$$F = \frac{M\,R\,T}{S}$$

Now the spontaneous mutation rate and the rate of induced mutation (s and m) are much better known for flies than for man (S and M). Thus, the procedure is to arrive at F by first finding as good a value as possible for f and then modifying this according to the relation,

$$F = f \times \frac{M\,R\,T\,s}{m\,r\,t\,S}$$

In his original presentation of the argument, Haldane adopted for f a value (0·001) which had been calculated by D. E. Lea (1946). However, it has recently been pointed out (Spiers, 1956) that Lea based his calculation on an estimate of natural radiation of 2·2 milliroentgens (mr) per day, which is about eight times greater than that accepted at the present time (paragraph 200). The value for f has to be reduced accordingly. For the sake of simplicity we have taken it as 0·0001 (paragraph 178), although this may be a slight underestimate.

This value for f is based on an estimate of 0·15 per cent sex-linked lethals. Lea argues, in agreement with other authors who have considered the matter, that there may be about 1,000 genes capable of mutating to sex-linked lethals in *Drosophila*; his value for the spontaneous mutation rate can therefore be expressed as $1{\cdot}5 \times 10^{-6}$ per locus. The statement (paragraph 178) that the human spontaneous mutation rate is probably about five times as great as this is based on the observation that the mutation rates of several human genes are around 10 per million per generation (cf. Table 1C).

The opinion (paragraph 179) that mouse genes are more sensitive to radiation than those of *Drosophila* (i.e. have a higher value for m) is based on the work of W. L. Russell (1954). It is disputed by some authors; but if one adopts it, and takes it to suggest the hypothesis that human genes are also more sensitive, the result is to increase the value of F, and thus to lower the estimate of the minimum representative doubling dose. In order to be as cautious as possible, we have therefore adopted these assumptions.

The estimate (paragraph 185) that one human germ cell in ten carries a new mutation is a minimum figure arrived at in calculations by H. J. Muller (1950, 1954).

Some typical figures for doubling doses derived from experiments on plants and animals are given in Table 1H. These figures are open to a wide margin of statistical error, as the number of spontaneous mutations was always small; in most instances values smaller or larger by a factor of 2 are not excluded.

There have been many other reports of experiments in which mutations were induced by ionizing radiations, especially in plants and lower organisms; however, in the great majority of these, either the control series was too small for any spontaneous mutation to be observed, or the apparent mutants found were not confirmed by genetic test. The figures quoted here are probably representative.

APPENDIX J

The Dose of Radiation Received in Human Tissues from Natural Sources

All living organisms absorb ionizing radiation from sources which are either present in their environment or incorporated in their own tissues. The most important 'external' radiations are cosmic rays and the radiations arising from elements of the uranium and thorium series present in the earth or the air and from the potassium 40 content of the earth and of vegetable matter. The 'internal' irradiation arises chiefly from the potassium in tissues, but there is also a small contribution from carbon 14 and in some cases soft tissues within bone receive radiation from very small amounts of radium present in the skeleton. Radon in the atmosphere, besides contributing its quota to the external radiation, may also add to the internal dose, by access of the radioactive material to the tissues via the lungs. Because alpha rays and beta rays are so readily absorbed, even by the elements of low atomic number which comprise the soft tissues, the dose from external sources may be regarded as entirely due to cosmic rays and gamma rays. The dose from internally absorbed radioactive materials, however, arises in large measure from beta rays and, when present, from alpha rays.

The radiation dose to human tissues from this normal background is small compared with doses known to cause immediate somatic change, and its significance is presumably to be sought in possible long-term effects; of these the genetic and carcinogenic actions of ionizing radiation would appear to be the most likely. The critical tissues considered in this appendix are, therefore, the gonads and the osteocytes of the Haversian systems in bone. An estimate of the dose to these tissues is made as far as present data allow, and although this is attempted for a number of different localities, it must be emphasised that knowledge of the basic data is far from complete.

All doses are expressed as soft-tissue doses in rads, and where calculations have involved the quantity 'W,' the energy per ion pair formed in air, a value of 34 eV has been taken as representative of recent experimental determinations of that constant.

SOURCES OF EXTERNAL RADIATION

Cosmic rays

The cosmic ray ionization intensity in air at sea-level (and geomagnetic latitudes above 41° N) has been variously quoted in the literature over a range of from 1·5 to 2·8 ion pairs/cc/sec. The differences have arisen largely in the interpretation of high-pressure ionization-chamber measurements, and the correct method of analysis appears to be that used by Clay and his co-worker (1938), and re-examined and supported by further experiments by Burch (1954). The mean of three values given by these workers and corrected to ionization in free air is 1·92 ions/cc/sec. Converting this value to a tissue dose gives:—

cosmic ray dose-rate to soft-tissues = 0·028 rad/year.*

This dose-rate applies to any soft tissues in the body, including the gonads and osteocytes, and is typical for most locations at the earth's surface above latitude 41° N. It may be some 20 per cent less in basements of tall buildings, which absorb the 'soft' cosmic ray component; but any considerable

* 1 rad corresponds to a dose of about 1·07 r in soft tissues.

reduction in dose-rate will only occur in deep underground situations. At a height of 10,000 ft. the cosmic ray dose-rate is increased by a factor of 3 or more, but it will be seen later that cosmic rays contribute only a fraction of the total tissue dose, and that, in consequence, the tissue dose-rate at this height might be only some 40 per cent greater than at sea-level.

The dose-rate of 0·028 rad/year is less than the figure 0·035 rad/year, given, for example, by Libby (1955). For the reasons given above, the lower figure appears to be the correct one and is retained in the present analysis. It is a matter of some discussion whether or not the small component of slow particles in cosmic radiation has a higher R.B.E. than the fast-meson component, the R.B.E. of which has been taken as unity. Some mutations are reported as being less effectively produced by heavily ionizing particles; in a few other cases the R.B.E. for heavy particles has been found to be in the region of 5. In the extreme case, the slow-particle component would not appear likely to add as much as 0·01 rad/year to the effective cosmic ray dose. On the other hand, some shielding of the soft gamma ray component of the cosmic radiation by building structures occurs, which reduces the dose below the unshielded value. It would seem best, in view of this and the possible effect of a higher R.B.E., to accept the unshielded value of 0·028 rad/year as the best estimate for sea-level and latitudes above 41° N.

Local gamma rays

Under most conditions of life, gamma radiation from local surroundings is responsible for the greater fraction of the external radiation dose. Measurement of this contribution, however, has been made in comparatively few places.

Some measurements of local gamma ray dose-rates in Leeds and Aberdeen (Spiers and Griffith, 1956) are summarised in Table 1J. The results cover only limited types of situation, but the concordance between the dose-rates in brick and concrete buildings, whether in Leeds or in Aberdeen, suggests that they may be fairly representative of the dose-levels in areas which are not specially radioactive and in buildings not made of granite. The dose-rates in Leeds determined with a lightly shielded counter, are about 20 per cent higher than the background measurements previously reported, but this effect was shown to be due to the difference in shielding in the two measurements. The results in Table 1J represent the local gamma ray dose-rates under conditions of light shielding.

TABLE 1J

Measurements of local gamma ray dose-rates in Leeds and Aberdeen (Spiers and Griffith, 1956)

Type of building (or 'out-of-doors')	Location	Local gamma ray dose-rate (rad/year)
I. All granite ...	(*a*) Aberdeen—laboratory	0·107
	(*b*) Aberdeen—bell tower	0·099
	(*c*) Aberdeen—entrance hall	0·101
II. Brick and concrete	(*a*) Aberdeen—rooms on various floors	0·073
	(*b*) Leeds—room in hospital building...	0·081
	(*c*) Leeds—single-storey laboratory ...	0·080
	(*d*) Leeds—various rooms in house ...	0·077
III. Out-of-doors ...	Leeds—garden of house II(*d*) above ...	0·048

Sievert and Hultqvist (1952) and Sievert (1955) have reported measurements of the total 'cosmic ray plus gamma ray' background in Swedish houses and in out-of-door situations. Some of the Swedish results are given in Table 2J where an allowance has first been made for the cosmic ray fraction and the residual ionization converted to tissue dosage. The mean dose-rates recorded were based on measurements in about 70 houses. Variations in dose-rate were most marked in Type 3 houses where, in some, values 50 to 100 per cent above the mean in Table 2J were recorded.

TABLE 2 J

Measurements of the total 'cosmic ray plus gamma ray' background in Swedish houses and in out-of-door situations in Sweden (Sievert and Hultqvist, 1952 ; *Sievert,* 1955)

Situation		Gamma rays only (ions/cc/sec.)	Mean dose-rate (rad/year)
Indoors, centre of room	Wooden houses	4·0	0·059
	Brick and concrete houses (Type 1)	6·2	0·091
	Brick and concrete houses (Type 2)	6·5	0·095
	Brick and concrete houses (Type 3)	14·8	0·216
Outdoors	Stockholm streets	5·8	0·085
	Over igneous rocks	3·9 to 8·3	0·06 to 0·12
	Over clay	3·4	0·05

The local gamma ray dose-rate can also be estimated approximately at some places in South-west England from geiger-counter recordings reported by Peirson (1951). Taking the counting rate given by Peirson for a 'normal' background situation, and allowing for the cosmic ray fraction, a counting rate of about 1·3 cts/min. per cm^2 of projected cathode area is deduced for this 'normal' local radiation. Assuming an over-all efficiency of the counter assembly of 0·6 per cent, and a mean gamma ray energy of 1 MeV, a gamma ray flux is deduced which corresponds to a tissue dose-rate of 0·05 rad/year, a figure reasonably in accord with measurements in Leeds and in Sweden away from areas of high radioactivity. Applying the same analysis to the recorded counting rate in St. Ives and its neighbourhood, the local gamma ray dose-rate is deduced as approximately 0·25 rad/year. Great accuracy cannot be claimed for this estimation in view of the assumptions made, but it is of the same order as the values given in Table 2J for areas of known high radioactivity in Sweden. Dose-rates of 0·3 rad/year and over have been reported in some parts of Cornwall (Wood and Willey, 1954).

Atmospheric radon

Radiation from the break-down products of atmospheric radon also add to the external gamma ray dose. This effect may be expected to be small under most conditions, but so far no measurements have been made to distinguish its contribution from that of gamma rays from the solid surroundings. Peirson and Franklin (1951) have calculated that at ground level an atmospheric radon content of 3×10^{-13} c/l produces a gamma ray flux of the order of 10 quanta/cm^2/min. Taking a mean energy of 0·8 MeV for radium B and C gamma rays, the tissue dose-rate for this flux is 0·0022 rad/year. Anderson, Mayneord and Turner (1954) have reported levels of atmospheric radon in London (in May 1953) which averaged $2\text{–}3 \times 10^{-12}$ c/l. and under these conditions the external gamma ray dose from atmospheric radon is of the order 0·02 rad/year—a contribution of nearly the same magnitude as that due to cosmic rays.

SOURCES OF INTERNAL RADIATION

Potassium 40

The following data have been used in the calculation of the dose-rate from the potassium content of the body:—

Mean potassium content of body	= 0·215 per cent
Specific β-activity of K	= 27·4 β's/sec./g. K
Specific γ-activity of K	= 3·5 γ's/sec./g. K
Mean β-ray energy of K 40	= 0·605 MeV
Mean γ-ray energy of K 40	= 1·46 MeV

Because the mean range of the beta particles of potassium 40 is only some 2 mm, the dose-rate in a given organ is determined mainly by its own potassium content. In the absence of precise values for the potassium content of the gonads, the mean for the whole body, derived from Shohl's data (1939) is adopted. The total tissue dose-rate derived from the energy released per g. of tissue, is then:—

$$\text{tissue dose-rate due to K} = 0{\cdot}018(\beta) + 0{\cdot}002(\gamma) = 0{\cdot}020 \text{ rad/year.}$$

In relation to this calculation there may be doubt as to the precise value for the potassium content of the gonads. So far it has only been possible to make flame-photometric measurements on tissues taken from two post mortem examinations. The results, obtained through the kind co-operation of Dr. F. M. Parsons of the Urological Department of the General Infirmary at Leeds, are as follows:—

Case and age		*Potassium content (mg./100 g.)*	*Sodium content (mg./100 g.)*
A. 67 yr. (testes)	(i)	190	205
	(ii)	240	172
B. 28 yr. (ovaries)	(i)	188	200
	(ii)	197	204

Three results are concordant and one (Aii) is suspect in that the sodium value is so low. They suggest, however, that no great error is being made in assuming an average potassium content of 0·215 per cent, as given by Shohl. The tissues were taken from the central parts of the gonads, and the potassium content should be representative of the average value over dimensions of a few mm. of the tissues containing the germ cells.

Carbon 14

Carbon in living systems contains approximately 1 part carbon 14 in 10^{12}, and has a specific beta ray emission of 0·2 beta particles per sec per g. carbon, with a mean energy of 0·053 MeV. Taking the carbon content of tissue as 18 per cent, the energy deposition due to the carbon 14 amounts to a tissue dose-rate of only 0·001 rad/year.

Radon and its disintegration products

An estimation of tissue dose arising from the inhalation of air containing radon can be made if, in the absence of complete information on all the factors concerned, some simplifying assumptions are made. The concentration of radon in the atmosphere is regarded as uniform, and it is assumed that the break-down products (radium A, B, C and C^1) are in equilibrium with the radon and are uniformly suspended in the air. The calculation is then made in two parts: (1) for a steady level of radon (plus disintegration

products) in body-tissues via the blood in contact with the radon in alveolar air, and (2) for a steady intake into the lungs of the disintegration products formed in the air.

The solubility of radon in water at 37° C. is 0·17, and in fat the figure is about five times higher. If the concentration of pure radon in alveolar air is C, and is regarded for the moment as free of disintegration products, the concentration of radon in the 50 kg. of aqueous tissue will be 0·17 C and that in the 10 kg. of fatty tissue will be 0·85 C, giving a mean for the whole soft tissues (63 kg.) of 0·27 C. This level of radon in the tissues is maintained, and hence it will maintain its disintegration products in equilibrium with it. Taking the effective disintegration energy of the series as 20 MeV, and assuming an atmospheric radon content of 3×10^{-13} c/l (as above) the energy deposition per g. of tissue corresponds to a dose-rate of only 3×10^{-5} rad/year, mainly of alpha radiation. Using an R.B.E. of 10 to enable this alpha dose-rate to be added to the beta and gamma dose-rates already calculated, the tissue dose-rate for the dissolved radon is 3×10^{-4} rem/year.

The dose-rate from the disintegration products formed in the atmosphere and subsequently inhaled can be calculated on an assessment of the fate of the products retained. If the products are insoluble in body fluids, little if any irradiation of the gonads could occur from inhalation; if soluble, a fraction of the retained products (the retained fraction in lungs and respiratory tract is 75 per cent, I.C.R.P., 1955) would be generally disseminated in the bloodstream. The calculation has been based on the assumption that 20 per cent of the inhaled disintegration products are effective in irradiating general body-tissues, and an exact formula has been used in calculating the equilibrium energy dissipation. The total dose-rate to soft tissues due to the inhalation of air containing 3×10^{-13} c/l of radon plus disintegration products is then 1·9 millirem per year.

The total dose-rate to soft tissues due to the inhalation of air containing 3×10^{-13} c/l of radon plus disintegration products might be expected, therefore, to be about 0·0022 rem/year. At the radon concentration of 3×10^{-12} c/l reported by Anderson *et al.*, (1954) for London air the dose-rate thus calculated would be 0·022 rem/year, i.e. a figure comparable with the cosmic ray background.

Total dose-rate to the gonads

Before summarising the total gonad-dose from all sources the effect of body-shielding on the local gamma ray dose should be considered. Measurements have now been made of this shielding factor by using a water-filled tin model. A thin-walled tube was fixed in the trunk so that a small geiger-counter could be positioned at the site of an ovary. The counter was placed

TABLE 3J

The screening factors for local gamma rays: horizontal, sitting and standing postures

Position of model	Screening factors for local gamma rays			
	Female	Mean	Male	Mean
Horizontal	0·52		0·67	
Sitting	0·58	0·56	0·70	0·70
Standing	0·59		0·72	

Mean factor for both sexes 0·63

outside the trunk to assume representative positions for the testes. Measurements were made in a laboratory (site IIb in Table 1J) where the background was known to be steady. The cosmic ray response of the counter was allowed for by measurements made inside a cubicle shielded by a minimum thickness of 9 in. of steel. The screening factors for horizontal, sitting, and standing postures are given in Table 3J.

The correction for the cosmic ray component inside the building could only be estimated approximately, but if this were in error by as much as ±100 per cent it would produce errors in the screening factor of not more than −8 or +4 per cent. In the male, the factor varies with the position assumed but by not more than ±8 per cent. The average ratio for the two sexes should not be in error, therefore, by as much as ±10 per cent.

Summary of dose-rates to the gonads

Table 4J summarises dose-rates which may be regarded as typical for regions in this country and possibly elsewhere, where the local rock radioactivity is not specially high, and the buildings are of brick or concrete construction not incorporating specially radioactive materials such as granite or granite chips. In arriving at the dose-rates a gonad shielding factor of 0·63 has been assumed, and the local gamma ray dose is averaged for an assumed 8 hours* out-of-doors and 16 hours indoors.

TABLE 4J

Dose-rates to the gonads for a region of 'normal' ground radioactivity

Radiation source	Dose to gonads per year (rad)
External irradiation	
Cosmic rays (sea level)	0·028
Local gamma rays (Leeds, 78 millirad/year indoors ... 48 millirad/year out-of-doors)	0·043
Radon in air, 3×10^{-13}c/l	0·001
Internal irradiation	
Potassium 40	0·020
Carbon 14	0·001
Radon + disintegration products, 3×10^{-13}c/l	0·002
Total dose per year	0·095†
Dose to age 30 years	2·85†

† Includes allowance for the R.B.E. of the alpha radiation where present, and therefore also expresses the gonad-dose in rem.

Table 5J illustrates an attempt to assess the gonad-dose to populations in three different localities and in different types of building. Estimates are given for two radon-in-air concentrations but it is not known whether levels as high as 3×10^{-12} c/l persist for long periods.

It should be noted that higher dose-rates and greater differences between localities could be obtained by taking the extreme values observed in some of the Stockholm and Aberdeen sites, but an attempt has been made to assess as far as possible the conditions affecting large numbers of people. Thus, because even agricultural workers spend probably 8 hours per day or more

* This is a maximum figure and is probably an over-estimate.

TABLE 5J

Assessment of the gonad-dose to populations in three different localities and in different types of building

Location	Type of building	Dose to gonads (rad per year)*	
		Radon 3×10^{-13} c/l	Radon 3×10^{-12} c/l
Leeds	Brick	0·095	0·125
Aberdeen	Granite	0·108	0·138
Stockholm	Wood houses ...	0·095	0·125
	Type 2 houses ...	0·109	0·139
	Type 3 houses ...	0·160	0·190

* Gonad shielding factor, 0·63; exposure, 8 hours out-of-doors and 16 hours indoors.

in a brick house, their gonad-dose is not very different from that calculated for a Leeds town-dweller. The body-shielding factor of 0·63 considerably reduces the difference otherwise apparent in situations of differing local radioactivity.

DOSAGE IN BONE

Consideration should be given to the problem of dosage in bone from natural sources, in order that the significance of the ingestion of bone-seeking radioactive isotopes may be properly assessed. The dose-rate to osteocytes has been estimated, therefore, by a summation of the dose-rate from sources external to the bone and that from radium deposited in the skeleton itself.

Dose from sources external to bone

The dose-rates to osteocytes from the sources considered above will not be very different from the tissue doses already calculated. The dose-rate from potassium 40 will be less, because the potassium content of the bone is only about one-quarter of that for the body as a whole. The dose-rate from inhaled atmospheric radon and its products may also be expected to be greatly reduced, because even if the radioactive content of an osteocyte from these sources were the same as that deduced for soft tissues, the alpha particles would leave only a small fraction of their energy in the osteocyte itself. The reduced dose-rate to osteocytes for the conditions assumed in Table 4J might be put at about 0·08 rem/year.

Dose from radium in bone

The most likely value for the radium content of the skeleton for a region not exceptionally high in radioactivity would appear to be the mean content of $1·2 \times 10^{-10}$ g. measured by Hursh and Gates (1950) for subjects in Rochester, New York, U.S.A., where the radium content of drinking-water is given as $0·6 \times 10^{-16}$ g./cc. If the skeletal radium is proportional to the radium level in drinking-water, the measured level of $1·1 \times 10^{-15}$ g./cc for tap water in St. Ives (Gleuckauf and Jacobi, 1953) would imply a body radium content of $2·2 \times 10^{-9}$ g. Swedish waters are known to have very much higher radium contents, implying body radium contents approaching 10^{-7} g., but measurements of body gamma ray emission by Sievert (1953) do not suggest radium contents of this order. In fact a cross-check in 1953 between Sievert's apparatus and one in Leeds indicated that measured activities of persons not occupationally exposed to radium salts were about the same in Stockholm

and Leeds. These measurements, however, do not exclude small skeletal-radium burdens of the order of 5×10^{-9} g.*

A mean radium-burden of 10^{-10} g. has been taken as typical for a region not specially radioactive, and a mean burden of 10^{-9} g. of radium for an active region like St. Ives. Using methods similar to those given by the author elsewhere (Spiers, 1953) the mean dose-rates to osteocytes have been estimated as in Table 6J.

TABLE 6J

Estimation of the mean dose-rates to osteocytes

Conditions	Ra in skeleton (g.)	Dose-rate to osteocytes (rem/year)		
		Ra	External sources	Total
Not specially active region, e.g. Leeds 3×10^{-13} c/l radon in air ...	10^{-10}	0·037	0·08	0·12
Active region 3×10^{-12} c/l radon in air ...	10^{-9}	0·37	0·18	0·55

* Recent work in America and in Germany has confirmed the value for the skeletal-radium burden as about 10^{-10}g., and suggests that burdens greater than 10^{-9}g. are unlikely.

APPENDIX K

The Genetically Significant Radiation Received from Diagnostic Radiology

The total number of X-ray examinations performed per annum

Information under this head relating to the National Health Service has been obtained from the Annual Reports of the Ministry of Health. Other information was supplied by the Services, other Government departments, and various bodies which undertake diagnostic examinations.

Hospitals operating under the National Health Service are responsible for by far the biggest proportion of the X-ray diagnostic work carried out in this country. Total figures for the number of X-ray examinations performed at these centres are available for the years 1951 and 1952; for the years 1953 and 1954 however the only information given is the number of 'units of work done'. Between 1951 and 1952 the number of examinations carried out under the National Health Service (Table 1K) increased by 13·2 per cent, and between 1953 and 1954 by 10·9 per cent. It has, therefore, been assumed that the mean of these figures, 12 per cent, would fairly represent the increases for 1952–53 and 1954–55. The number of examinations carried out in 1954 was estimated by applying to the number of 'units of work done' the ratio derived from the previous year's figures, i.e., that 1 examination equals 1·8566 'units of work done'. The figure for examinations performed in 1955, estimated on the assumption that the trend shown in the previous years continues, is, therefore, approximately 12,200,000.

TABLE 1K

The number of X-ray examinations per year carried out at National Health Service hospitals: 1951–55

Year	Number of 'units of work done'	Number of examinations
1951	—	7,738,389*
1952	—	8,756,643*
1953	18,214,310*	9,810,365†
1954	20,201,177*	10,880,506‡
1955	—	12,189,801†

*From the Annual Reports of the Ministry of Health.
†Obtained by adding 12 per cent to the figure for the previous year (see above).
‡Obtained by applying to the number of 'units of work done' the ratio derived from the previous year's figures, i.e. that 1 examination equals 1·8566 'units of work done'.

This total refers only to National Health Service hospitals. It has been assumed that hospitals outside the Health Service undertake 3 per cent of this number of examinations, i.e., 350,000, and that private medical practice accounts for a further 100,000 examinations. It is further assumed that the distribution between types of examination and sex and age of the patients examined is sufficiently similar to justify the final total of 12,650,000 being treated as a single group.

The gonad dose per examination

The values used in the calculations for radiation dose to the reproductive organs are listed in Table 2K. They are based almost entirely on the work of Stanford and Vance (1955). These workers made careful measurements on more than 1,500 patients, largely at one hospital. For males, the measuring instrument was placed close to the testes; for females, at a point on the skin over the ovaries. A subsidiary experiment on six cadavers gave the ratio of ovary-dose to surface-dose to be expected for the different kinds of X-ray examination; it did not, however, give any indication of the dose received by the reproductive organs of a foetus. Accordingly, where the site of examination is remote from the pelvis of a pregnant woman, the dose to the foetal gonads is taken to be the same as that to the mother's ovaries; where the child is in the direct beam, however, the dose has been estimated from the information given by Stanford and Vance. For salpingography and pelvimetry, the doses used are the lowest that have been published in this country. In the case of pelvimetry, it is assumed that three films are taken in each examination, although many hospitals take more. The dose for salpingography is as reported by Barnett and Bewley (1955) and that for the foetal gonads in pelvimetry by Stanford (1951).

It must be emphasised that the doses quoted in Table 2K are those produced by the techniques and methods of only one hospital; further, this hospital is one where particular care is taken to reduce the gonad doses to the minimum.

TABLE 2K

The dose of radiation received by the gonads in the course of X-ray diagnostic examination of various parts of the body

‡ n = negligible (i.e. below 0·1 per cent).

§ Allocated between the sexes in the sex-ratio at birth, 1 : 1·059.

Classification of examinations by sex and age of patient and by type of examination

Information as detailed as this is not readily available in many hospitals. It has, however, been obtained for 2 London teaching hospitals, 2 general non-teaching hospitals in the Greater London area, and a children's hospital. In the few cases where appreciable discrepancies exist, weighting was in favour of the non-teaching hospitals. Information on the number of pelvimetry and obstetric abdomen examinations carried out was obtained from 9 hospitals, 5 of them outside London. Apart from these two types of examination, the number of unborn children exposed to radiation was calculated from the number of women of childbearing age examined.

Detailed results

The results of the calculations on the genetically significant radiation received from diagnostic radiology are given in Table 3K. The number of examinations has in each case been expressed as a percentage of 17,650,000, the estimated total number of X-ray examinations of all kinds performed in England and Wales in 1955. The doses received, weighted according to the age of the patients exposed, are expressed as percentages of the total genetically significant dose from diagnostic radiology in England and Wales in 1955.

For comparison, the genetically significant radiation dose from natural radiation has been similarly calculated. Dose rates of 0·10 rad per year for males, and 0·09 rad per year for females have been assumed, and weighted according to the ages of the population as a whole. The total radiation received from diagnostic radiology is found to be 22 per cent of that received from natural radiation by the whole population, and is in addition to it.

Strictly, these figures apply only to England and Wales, but there is no reason to think that the corresponding figures for Scotland and Northern Ireland will be greatly different. Each approximation in the calculation has, however, been estimated on the low side. According to the calculations based on the present sample, therefore, the value of 22 per cent should be regarded as a probable lower limit rather than as an estimate. A realistic estimate of the radiation contribution from diagnostic radiology might be considerably greater than this figure.

A more detailed presentation of the subject than is possible here has been prepared and is to be published shortly (Osborn and Smith, 1956).

APPENDIX L

The Contribution of Occupational Exposure to the Genetically Significant Dose of Radiation

In order to calculate the amount of radiation contributed to the total gonad-dose by occupational exposure, it is necessary to know (*a*) the number of persons, distributed by sex and age, who are exposed to radiation in the course of their work, and (*b*) the average gonad-dose received per person exposed. Accurate information on these points is lacking at the present time, and the following estimate is based on the best available data.

An estimate of the average gonad-dose per worker can be made by analysing the data obtained by the radiation monitoring service operated at one time by the National Physical Laboratory and now by the Radiological Protection Service; this service measures the occupational exposure to radiation for workers in the fields of medicine, research and industry, excluding the Atomic Energy Authority. It is a voluntary service and its coverage is incomplete, since many organisations, particularly hospitals, carry out their own monitoring, and there are undoubtedly others where no monitoring is done. However, the average dose recorded by the N.P.L. Service is a low one, and all the available evidence suggests that the doses recorded by the self-monitoring organisations are of a similar order. In these circumstances it has been assumed that the data obtained by the N.P.L. Service are applicable to all workers, except dentists in private practice; analysis of these data gives the figure of approximately 50 mr per week, or about 2·5 r per year, as the average gonad-dose for both males and females in all occupations.

Practically no information is available about private dentists and their assistants, but it is clear that, taking into account the number and type of examinations involved, their exposure risk is very much less than that of radiologists and radiographers; given reasonable care, the average gonad-dose they receive will be considerably lower than the figure of 2·5 r per year just quoted.

Besides those persons actually working with irradiating equipment, there are large groups of people, for example nurses in hospitals, who are exposed to some extent as a result of their work-places being near a source of radiation. These people are not regarded as being radiation workers and are not monitored; their total number however, greatly exceeds that of the radiation workers, and although the average doses are very low, the aggregate dose is undoubtedly significant.

From the Annual Reports of the Ministry of Health, it would appear that there are at present about 9,000 persons, excluding private dentists, occupationally exposed in the medical field; and it is estimated from information supplied by the Factory Department of the Ministry of Labour and National Service that there are about 5,000 persons occupationally exposed in the field of industry and research. This total of 14,000 persons is divided roughly equally between the sexes, and these are the people to whom the figure of 2·5 r per year is considered to apply. Thus, the gonad-dose received per year by this group as a result of occupational exposure, is 17,500 r to each sex. In order to allow for the group of workers exposed at a low level mentioned

above, it is considered advisable to increase this aggregate dose by about 50 per cent, i.e. to 25,000 r per year, for each sex; and a further 1,000 r should be added for each sex to cover the doses likely to be received by those private dentists who possess X-ray equipment, and by their assistants. The final total, which, it will be appreciated, is a very rough estimate, would then be 26,000 r each for males and females.

There is, unfortunately, no precise information about the age-distribution of these groups, and the best assumption that can be made at the present time is that the females are all below the mean age of reproduction (for women, about 28 years) and that the males are evenly distributed between the ages of 18 and 60 (mean age of reproduction about 32 years).

The total number of females below the age of 28 in the United Kingdom is 10×10^6. Each of these women receives a gonad dose from natural radiation of about 0·1 r per year, so that the total dose-contribution from natural radiation to this part of the female population is 10^6 r per year. Hence, at the present time, the occupational dose adds about 2·6 per cent to the genetically significant dose of natural radiation received by the female population.

For males in the United Kingdom, the population is about 5×10^6 between the ages of 18 and 32, and about 9×10^6 between the ages of 32 and 60. Only the dose-contribution for workers aged up to 32 is effective, so that the occupational exposure of genetic importance for male workers is about 9,000 r per year. The total number of males in the United Kingdom below the age of 32 is about 12×10^6, so that this section of the population receives a total dose from natural radiation of $1{\cdot}2 \times 10^6$ r per year. Thus, the occupational dose constitutes an addition of about 0·75 per cent.

Accordingly, in the United Kingdom the occupational contribution to the genetic dose from all sources except the Atomic Energy Authority is 26,000 r per year for females and 9,000 r per year for males, i.e. 35,000 r per year in all. The dose of natural radiation received by females up to the age of 28 is about 10^6 r per year, and by males up to the age of 32, about $1{\cdot}2 \times 10^6$ r per year, making a total of $2{\cdot}2 \times 10^6$ r per year. Hence, on the basis of the assumptions made, the occupational dose adds about 1·6 per cent to the genetic dose received by the population from natural radiation. It is to be noted that the contribution from the Atomic Energy Authority, reported by Farmer (1956), is 0·09 per cent.

I should like to thank Dr. G. H. Aston of the National Physical Laboratory and Mr. K. L. Goodall of the Factory Department, Ministry of Labour and National Service, who supplied some of the information on which the above estimates are based.

APPENDIX M

The Long-range Fall-out from Nuclear Test Explosions

This appendix summarises the data available on the radiation dose to human beings resulting from the fall-out from distant nuclear explosions. Continuous measurements have been made since 1951 by the Atomic Energy Research Establishment, Harwell, of the deposition on the ground of fission products from distant nuclear explosions. Measurements have also been made of the activity in the air at ground level in the United Kingdom, and on several occasions the variation of activity with height has been explored in the atmosphere up to 50,000 ft. (Stewart, Crooks and Fisher, 1955).

Diffusion and deposition of dust clouds from nuclear explosions

The dust cloud from a weapon in the 'nominal' size-range generally remains within the troposphere, reaching a maximum height of some 25–40,000 ft. when exploded in the middle latitudes. This part of the atmosphere is comparatively turbulent, and as the cloud travels downwind it diffuses both laterally and vertically and contaminates the lower atmosphere across a broad front at great distances. The dust is ultimately removed from the atmosphere by washout in rain-water and by direct deposition on to surfaces. Measurements made in the United Kingdom have shown that the former is the more important process and that the latter can be neglected in comparison; this conclusion however is not necessarily true close to the test site, where gravitational deposition may be an important factor. The United Kingdom measurements have also shown that, on the average, one half of the fine dust from the smaller type of nuclear explosion is removed from the atmosphere by rain-water in a period of 22 days. Deposition of the dust cloud from such explosions is therefore effectively complete within 3 months of the time of burst.

The behaviour of the clouds from explosions in the megaton class is markedly different. These clouds penetrate into the stratosphere, and may reach heights of the order of 100,000 ft. Diffusion is a very slow process in the stratosphere, and material returns to the lowest layers of the atmosphere at a much slower rate than in the case of the smaller type of explosion; a significant fraction of the dust generated may remain in the stratosphere for years after the weapon is exploded. Systematic surveys of the radioactive content of the air at various altitudes, taken in conjunction with fall-out measurements made at the same time, have shown that the dust from these tests was being deposited at a rate of between 10 and 20 per cent per year.

Measurement of airborne dust at ground level

The concentration of radioactive dust in the atmosphere has been measured routinely by drawing measured volumes of air through filters and counting the resultant beta activity on a suitable geiger-counter. Ground-level measurements made at Harwell since 1951 have shown that the activity present in air is of less biological significance than that deposited on the ground. The average level of activity from nuclear explosions has been found to be less than 1 per cent of that due to natural radioactivity in the air, and the maximum level has never exceeded that due to natural radioactivity. The measurements also show that over the past 7 years an individual in the United Kingdom might, on the average, have inhaled a total of $3{\cdot}4 \times 10^4$ dpm of fission products, including $8{\cdot}7 \times 10^3$ dpm of fresh fission-products

(measured at an age of 10 days) and including the particles of relatively high individual activity (Heard, 1956). The remaining $2 \cdot 5 \times 10^4$ dpm consisted of particles of low activity, owing to their low specific-activity or prolonged radioactive decay whilst airborne. For comparison, the continuous occupational permissible breathing-level for strontium 89 dust is $1 \cdot 3 \times 10^6$ dpm *per day* over a working life. Table 1M summarises information on the particles which might have been inhaled, deduced from the detailed 'particle-size and activity' analysis. Only particles in the high and medium specific-activity groups are considered; particles in the lower specific-activity groups are of less individual importance.

TABLE 1M

Estimate of the probable number of radioactive particles in the high and medium specific-activity groups, inhaled by any given individual in the United Kingdom over the past seven years

Particle size (μ)	High specific-activity		Medium specific-activity	
	Probable number inhaled	Total activity per particle* (dpm)	Probable number inhaled	Total activity per particle* (dpm)
1–2	7	$5 \cdot 4 \times 10$		
2–3	1	$2 \cdot 5 \times 10^2$		
3–6	0·5	$1 \cdot 4 \times 10^3$	112	14
6–9	0·07	$6 \cdot 6 \times 10^3$	14	66
9–12	0·01	$1 \cdot 8 \times 10^4$	3	180

* Immediate half-life = 6 days.

The particles carry fission-product beta activity which decays approximately inversely with time, and the activities quoted in Table 1M are those at 10 days after burst. The only significant alpha activity in the particles is that of plutonium. The activity of a 10 μ-particle may vary from about 4 disintegrations *per day* to extremely low levels. The mean concentration of this alpha activity in the ground-level air over the period has been 2×10^{-17} μc per cc compared with the occupational maximum permissible limit of 2×10^{-12} μc per cc (International Commission on Radiological Protection) for breathing insoluble plutonium dust over an occupational lifetime.

Measurements of deposition

Measurements of the deposition of the activity have been carried out at Milford Haven and at Chilton, near Harwell, since 1951, and in New Zealand since February 1955. In the current system, rain-water falling on a 12 × 10 ft. polythene roof is passed through a cylindrical esparto-grass filter and is collected in a tank. The beta activity of the dried filter is measured by mounting it co-axially over a calibrated cylindrical geiger-counter. Samples of the filtered rain-water are evaporated and counted on the same counting system, so that a correction can be made for the solubility of the radioactive material. This measurement is made only periodically, since experience has shown that the solubility of material from any particular bomb-series does not vary significantly with age, and it is possible to use a mean figure.

The daily deposition records at Chilton and Milford Haven are generally similar, although they occasionally differ markedly in detail. All daily deposits

of surface activity greater than 5 mc per sq. mile observed between February, 1951, and December, 1955, have been arranged in groups, and the frequencies of occurrence of the various groups are given in Table 2M.

TABLE 2M

The range of values of all daily deposits of surface activity greater than 5 mc per sq. mile, observed at Chilton and Milford Haven between February, 1951 *and December,* 1955

Range of values of deposited activity (mc per sq. mile)	Frequency of occurrence	
	Chilton	Milford Haven
5– 25	83	76
26– 50	9	5
51–100	3	1
101–150	3	—
151–200	1	—
201–250	—	1

The highest daily deposit at the sites was 190 mc per sq. mile at Chilton and 240 mc per sq. mile at Milford Haven; these occurred about the same time in heavy rain, some 5 days after the explosion of a weapon in Nevada in the autumn of 1951. The highest deposition in a single day from a thermonuclear weapon test was 25 mc per sq. mile at Chilton and 100 mc per sq. mile at Milford Haven.

The dose from deposited radioactivity

The gamma ray dose to human beings from each individual deposition of fission products has been calculated. Little difficulty has been experienced in dealing with the fission products from individual test series in which all the explosions take place within a period of a few weeks, or in interpreting the data when a series of nominal-bomb tests takes place in an atmosphere previously contaminated from thermonuclear tests; the difference in the time-scales of the deposition processes and in the decay-rates of the samples can be used to separate the components. The major difficulty arises when the stratosphere is contaminated with the fission products from thermonuclear tests widely separated in time. If, as we believe, the fine dust in the stratosphere is deposited at a rate of only 10–20 per cent per year, then it can be shown that more than 90 per cent of the integrated dose per generation is due to the single isotope, caesium 137.

The gamma ray dose from each individual deposition of fission products has been calculated, initially for the idealised case of an individual standing on an infinite flat plane. A protection factor of 3 has then been introduced to take account of the material which is washed into drains or is otherwise removed from the topmost layer of the earth's surface; this factor is believed to be conservative, since about one-half of the material already deposited has been found to be soluble in water. An additional factor of 7 has been allowed for the shielding provided by buildings* against the gamma rays from fission products; this figure has been derived from measurements carried out

* It is perhaps noteworthy that the reduction in dose from this cause is much less than the enhanced dose received from the gamma radiation from the natural radioactivity of the building materials (see Appendix J).

at the Atomic Energy Research Establishment with the gamma rays from cobalt 60, and is based on the assumption that the average individual spends $2\frac{1}{2}$ hours daily out-of-doors.

The individual doses have been summed, and the total external dose to be received by the average inhabitant of the United Kingdom due to material deposited on the ground from bombs exploded before 31st December, 1955, is estimated to be 1·7 mr. About 75 per cent of this dose is associated with material which has yet to be deposited; the dose due to bomb dust suspended in the air near ground level is negligible by comparison. It has also been estimated that if the various types of weapon continue to be fired at the present rates for an indefinite period, the ultimate dose per individual per generation of 30 years will be 26 mr; this level will be reached in approximately 100 years.

Very sensitive methods of measuring the radioactivity of the human body have been developed in recent years, and there has been some indication, on the records obtained in recent months, of the presence of a 0·6 MeV gamma ray, which is suspected to be due to the fission-product caesium 137 arising from the fall-out; it is not yet possible, however, to identify this radiation rigorously. The radiation has been observed qualitatively on body-monitoring records obtained at Harwell, and has been reported in some detail in progress reports from the Argonne National Laboratory in the United States. The highest body-activity detected so far in the United States is found to be 4×10^{-3} μc. This activity would, if maintained, produce a total-body irradiation of 0·6 millirad per year, or about 1/30 of the dose due to the naturally-occurring isotope potassium 40 in the body. The caesium activity in the body may be expected to fluctuate in step with the rate of fall-out, if the biological half-life is about 20 days as suggested by the International Commission on Radiological Protection, and if this activity in human bones arises from the direct contamination of herbage; in this respect the caesium differs markedly from the strontium 90, which is cumulative. From the quantities expected in the fall-out and from the chemical and metabolic properties of this isotope, the caesium 137 in the human body due to uptake from food and water is unlikely, on the basis of present information, materially to affect the dose, calculated above, from the fission products deposited on the ground.

The accumulation in the human body of strontium 90 from fall-out

The rate of deposition on the ground of strontium 90 in the fall-out has been measured by radiochemical analysis and, since the spring of 1954, has been found to be approximately 6 mc per sq. mile, per year. The total at 31st December, 1955, was 11 mc per sq. mile. From the measurements of activity in the upper air, it is anticipated that the total from bombs already fired will rise in about 10 years to a maximum of approximately 45 mc per sq. mile. Should the various types of explosion continue at the present rates, the accumulated deposition is likely to rise to an equilibrium value of about 500 mc per sq. mile in about 100 years' time.

Because of its similarity to calcium, strontium is found to follow this element in the human food-chain. Measurements have accordingly been made of the strontium 90 activity per g. of calcium in samples of vegetation and soil from a number of locations in the United Kingdom (Bryant and Chamberlain, 1956). Using refined radiochemical techniques and anti-coincidence counting procedures, the activity per g. of calcium has also been measured in the bones of yearling sheep, in samples of milk, and in human bones. The representative figure for the strontium 90 activity of vegetation in the autumn of 1955 was about 35 μμc per g. of calcium. The corresponding representative

figure for sheep bones was 14 μμc per g. of calcium but in a few mountain pasture areas, values up to ten times higher have been recorded.

The maximum activity found so far in the limited number of human bone-samples in the United Kingdom is 1·2 μμc per g. of calcium in the skeletons of one-year-old children. Adult bones show lower activities, ranging from 0·05 to 0·2 μμc per g. of calcium. These levels may be compared with the maximum permissible level for strontium 90 in the body for occupational workers, recommended by the International Commission on Radiological Protection, which corresponds to about 1,000 μμc per g. of calcium. The average radiation dose to the bone from a level of 1 μμc per g. of calcium would be about 3 millirem per year, and may be compared with the dose to the bone from the background level of radium in the average person in this country (10^{-10}c), which is about 37 millirem per year, and from natural gamma radiation, which contributes about a further 80 millirem to the bone (see Appendix J).

APPENDIX N

An Attempt to Estimate the Hazard from the Ingestion of Strontium 90

During the last fifty years, information has been accumulating about the induction of cancer in man and various species of animals by ionizing radiation and radioactive substances. Much of the evidence is qualitative and we have still very little reliable quantitative information on which to assess hazards.

The main risk from the absorption of bone-seeking isotopes is the delayed production of changes in bone, sometimes followed by osteogenic sarcoma, as well as blood changes consequent upon effects in the bone marrow.

The best human evidence is from the clinical investigation of patients to whom radium salts were administered for therapeutic purposes some twenty-five to thirty years ago, supplemented by earlier studies on industrial workers including those who ingested radioactive luminous paint. One of the most characteristic features of the production of malignant tumours of all kinds by ionizing radiations and radioactive materials is the very long latent period, often in the region of twenty years.

From a consideration of all the available evidence, the maximum permissible level of radium permanently incorporated into the skeleton has been fixed by the International Commission on Radiological Protection for persons occupationally exposed as 0·1 microcurie. From a comparison of the toxic effects of strontium 90 as compared to radium in animal experiments, the corresponding maximum permissible level for strontium 90 has been fixed at 1·0 microcurie. It must be appreciated that the biological effects of the radium and its breakdown products are probably largely due to alpha particles, whereas strontium 90 with its associated yttrium 90 emits only beta radiation. These differences in the energies and nature of the radiations, as well as differences in the patterns of distribution of the radioactive materials in the bone itself, probably cause the differences in biological effects. Strontium behaves chemically very similarly to calcium in bone formation and it is therefore natural to associate the two elements. The maximum permissible level of strontium 90 in the human skeleton corresponds to 1,000 micro-microcuries of strontium 90 per gramme of calcium in the skeleton, and it is this concentration which determines the dose level.

However, this maximum permissible level has been fixed for a group of adults educated in relation to the risks, under medical supervision, and working under carefully controlled conditions.

It is well-known that growing bone takes up more of the bone-seeking isotopes such as strontium 90, and concentrates them in the rapidly growing portions of the bone. It is also well known that rapidly growing tissues, such as those of children, are often particularly radiosensitive. We must also conclude from the available evidence that the damage produced by radioactive materials in bone is an integrated effect over the whole time and dose of the radiation. Since the radioactive half-life of strontium 90 is long (28 years), any material incorporated during childhood has a longer time to act than material taken up in later life. The danger is a little mitigated by the fact that radioactive strontium may not be retained in bone for as

long as radium. The biologically effective half-life of strontium 90 together with its daughter product yttrium 90 has been estimated by the International Commission on Radiological Protection as 2,700 days.

Another factor which suggests caution is that it is well-known that the irradiation of tissues in inflammatory conditions is more likely to induce tumour formation than the irradiation of normal tissues, and such conditions are more likely to occur in the whole population than in the specially selected occupational group.

It is difficult to fix precisely the lowest level at which tumour formation and other effects have occurred, owing to the fact that in many instances the material ingested by the worker or patient has been an unknown mixture of mesothorium and radium, and this uncertainty complicates the estimation of dose since the rates of decay of these substances are very different (mesothorium 6·7 years half-life and radium 1600 years).

Examination of the results of ingestion of radium by humans makes it clear that in the fixing of the maximum permissible level there is no great safety factor involved. A suggestive destructive lesion (in the dentine of the teeth) has been observed in a patient who carried a body burden of approximately 0·15 microcurie of 'radium' (probably a mixture of radium and mesothorium). Of 44 patients investigated by Looney *et al.*, 36 had body burdens of 0·4 microcurie or more; clinically recognisable, but not malignant, bone lesions were observed in 32 of these. The lowest level of pure radium producing a bone sarcoma in this series was 3·6 microcurie. Sarcomata were seen in five other patients included in this study, but these patients may well have ingested a mixture of radium and mesothorium. Among these five, the lowest level associated with the production of a tumour was 0·52 microcurie of 'radium' (mixture).

If we assume, in accordance with the agreed international recommendations, that 1 microcurie of strontium 90 carries the same risk as 0·1 microcurie of radium, then with all these considerations in mind, it would be unwise to fix the maximum allowable concentration of radioactive strontium in the bones of the general population, with its proportion of young children, at more than one tenth of the level agreed for occupationally exposed persons. That is, the maximum allowable concentration should not be more than 100 micro-microcuries of strontium 90 per gramme of calcium.

As we consider the possible effects which might be produced at lower dosage levels (that is, below one tenth of the maximum permissible level) our ignorance increases still further and we can only rely upon extrapolation from limited animal experience. It is still not possible to give a certain quantitative answer to the question of the relationship between dose and the frequency of bone changes, induction of tumours, and other effects of the radiation. At very low dose levels the incidence is so small in animals that the existence of a threshold below which no effect occurs has been postulated.

It appears however that each unit quantity of radiostrontium absorbed by the bone confers a certain probability of bone-tumour formation, the tumour development time perhaps decreasing and the tumour incidence increasing with the dose. On the whole, the experiments seem in favour of a proportionality between the frequency of tumours produced in a given length of time and the amount of radioactive material in the body even at low dose levels.

If we again assume, in accordance with the agreed international recommendations, that one microcurie of strontium 90 carries the same risk as

0·1 microcurie of radium, and attempt in this way to estimate the effects at one-hundredth of the maximum permissible level, we provisionally conclude that the effects are unlikely to be detectable. Nevertheless, if the concentration in human bones showed signs of rising greatly beyond one-hundredth of that corresponding to the maximum permissible occupational level it would indicate the need for immediate consideration of the problem.

ATOMIC SCIENTISTS ASSOCIATION

Limited by guarantee

STATEMENT ON STRONTIUM HAZARDS

In view of the widespread concern about radiation hazards, the Council of the Atomic Scientists' Association decided to appoint a committee to study the whole problem, and to follow up the implications of last year's report of the Medical Research Council in the light of more recent information. There is particular concern at the present time about the effect of the radioactive strontium produced in H-bomb tests. The Council has, therefore, requested the committee to prepare a public statement giving its current assessment of this hazard.

The report of this committee (whose membership is given below) is as follows:

When an H-bomb is exploded at a high altitude, and in an area in which there are no inhabitants—as is said to be the case with the forthcoming British tests—there is very little likelihood of immediate injury to people, or of substantial local contamination of the oceans, even if a large amount of radioactivity is produced in the explosion. This radioactivity would be taken up into the upper regions of the atmosphere from where it would spread all over the globe and gradually descend to the ground over a period of some years. By that time only the long-lived radioactive products of the bomb would remain, and it is with the possible effects of these that we are concerned.

If H-bomb tests continue at the present rate, the dose of radiation to the reproductive organs, which may cause damage to future generations, has been estimated in the M. R. C. report to be of the order of 1% of that resulting from the natural level of radiations. Of greater import, however, is the damage which may result to the present generation, mainly from one radioactive substance—strontium-90. This substance enters into our food, chiefly in vegetables and dairy products, and it accumulates in the human body in the bones where it remains for a long time. Depending on the assumptions made about the distribution of strontium in bone, we calculate (see appendix) that by the year 1970 the radiation dose to bone from all the tests carried out up to the autumn of 1956 will range from 9% to 45% of the dose received from all natural sources, including the radium which is normally present in bone.

It is known that radioactive substances concentrated in the bone may give rise to bone cancers and other damage, and that the irradiation of bone marrow may result in leukemia, a type of cancer of the blood. The induction of bone cancers by the action of strontium-90 in the bone has been demonstrated in animals; in human beings the same effect has been observed with radium, which in some ways behaves like strontium. In all these cases, however, the amounts of radioactivity present in the bone were far greater than those that are likely to accrue from H-bomb tests. The question then arises how to apply these findings to very small doses. There is here a fundamental difficulty, in that the relationship between the damage produced and the amount of radiation is not known. If this relationship is such that there exists a threshold dose below which cancer cannot be induced, then it can reasonably be inferred that the small amount of strontium-90 which will accumulate in bone from the current H-bomb tests would not result in any harm. If, however, the number of additional bone tumours resulting from radiation is directly proportional to the dose, then even a very small dose will give rise to a small but definite probability of bone cancer. This means that in a very large population a certain number of people would contract this disease as the result of their having a small amount of strontium-90 in their bones.

The evidence is as yet inconclusive. Some animal experiments have been interpreted as indicating the existence of a threshold dose. On the other hand, in man, the occurrence of leukaemia caused by radiation suggests a simple proportional relationship. Unfortunately the question cannot be settled by experiment in a short period of time, nor is there strong guidance from theory. There is one theory of the origin of cancer (that it is due to somatic point mutation) which

implies a proportional relationship. Where the effects of strontium-90 are concerned the authorities in the M. R. C. report appear to be inclined towards the proportional hypothesis, for they state "On the whole the experiments seem in favour of a proportionality between the frequency of tumours produced in a given length of time and the amount of radioactive material in the body even at low dose levels."

If the proportional relationship is accepted, it is then possible to make a rough estimate of the number of bone cancers which may result from a given H–bomb test. The calculations given in the appendix show that an H-bomb of the type tested at Bikini in 1954, if exploded high in the atmosphere, may eventually produce bone cancers in 1,000 people for every million tons of T. N. T. of equivalent explosive power. (It has been stated that bombs hitherto exploded were equivalent, in aggregate, to 50 million tons, insofar as their strontium-90 fall-out is concerned.) These thousand casualties would be spread all over the world and occur in the course of several decades. A somewhat larger number of people might suffer other bone changes, possibly without manifesting any clinical symptoms. There is also the probability of a number of cases of leukaemia resulting, but we have not enough data to estimate this number. At the same time it should be pointed out that these casualties, although large in absolute number, represent only a fraction of those due to the natural level of radioactivity; there would be no way of distinguishing one from the other.

If other types of nuclear weapons were exploded, the number of casualties would vary in direct relation to the amount of fission products released into the upper atmosphere.

In giving these estimates it must be emphasized again that, apart from the considerable margin of error due to lack of adequate data, they are based on the as yet unproved hypothesis of a proportional relationship applying to very small doses. From this point of view they represent the most pessimistic approach. On the other hand, if this hypothesis is correct, then the figures may be an underestimate of the damage since they do not allow for the radiation dose in children before or after birth. Children are known to take up much larger quantities of strontium than adults and the likelihood of producing radiation damage in them is probably much greater for the same amount of radiation.

APPENDIX

Estimate of strontium-90 hazard based on an assumed linear relationship between bone tumour formation and dose

1. The measurements of the ^{90}Sr content in human bone in this country, carried out by workers of the U. K. A. E. A.[1] show that by the beginning of 1956 the average amount in all age groups from 10 years upwards, was about 0.2 S. U. (1 S. U.=10^{-12} curies of ^{90}Sr per gramme of calcium).

2. If this figure is applied to the data of the world survey of strontium-90 made by the Lamont group,[2] we conclude that the ^{90}Sr concentration resulting from all the tests carried out up to the autumn of 1956 will in 1970 amount to about 4 S. U. This value is in agreement with the estimate of 4–10 S. U. made by Libby [3] for the U. S. A.

[3] W. F. Libby. Proc. Nat. Acad. Sci., 42, 945, 1956.

3. The total fission yield from the tests carried out up to the autumn of 1956 is estimated[2] to be equivalent to 50 megatons. For one nominal high-yield weapon (as defined in the Indian Government's document:[4] 20 megatons with high fission yield) exploded high in the atmosphere, one may therefore expect a concentration in bone of 1.6 S. U.

4. From Hasterlik's survey[5] of bone sarcoma in people with a radium burden, we estimate that 0.1 microcurie of radium yields about 0.5% probability of bone sarcoma. (A factor of 2 has been allowed for the possible admixture of mesotherium with the radium.)

5. Since 0.1 microcurie of radium is accepted[6] to be equivalent to 1,000 S. U., applying this probability value to the population of the whole world (2.5×10^9 people) we obtain that the number of bone sarcomas from one nominal high-yield nuclear test may amount to 20,000 all over the world ($2.5\times10^9\times0.5\times10^{-2}\times1.6\times10^{-3}$).

6. The radium normally contained in the body and the external radiation from natural sources deliver to the bone a dose equivalent to 45 S. U., or 9 S. U. if one allows for the non-uniform cohcenaration of strontium in bone (Spiers[7]). This means that the dose rate from strontium in bone will amount to 4/45 or 1/9 of that due to the natural background.

Radioactivity in Man and His Environment

Presidential address[1] by F. W. Spiers, D. Sc., Department of Medical Physics, The University of Leeds

A tradition, upheld almost without exception in the long history of the Röntgen Society and the British Institute of Radiology, is the delivery of an address to the Institute by the President during his term of office.

I am very conscious of the honour that falls to me to address you as President and very much aware of the responsibility of following my distinguished predecessors in the fulfilment of this obligation. In recent years, by a change of Articles of Association, the Institute has re-emphasised a characteristic that has always been implied by the nature of its membership—a wide interest in all that pertains to the science of radiation and radioactivity. Many presidential addresses given in this house bear witness to the activities and interest which spring from the Institute's constitution and to the bonds of cooperation and of service to radiology which exist between its medical and non-medical members.

It seemed appropriate, therefore, that I should speak on this occasion about radioactivity in man and his environment and give thereby a practical example of the width of interests encompassed by the Institute. Moreover, the subject I have chosen is of interest and importance to all who use ionizing radiation and is one which, although having significance in the problems of today, has also the historic interest of belonging to the scientific discoveries of the early years of this century.

The experiments of Elster and Geitel and of C. T. R. Wilson in the year 1900 first revealed the presence of a residual ionization in an electroscope and subsequent work by many investigators in the next few years showed that this ionization arose from radioactivity in the materials of which the electroscope was made, from terrestrial sources outside the electroscope and from penetrating radiation of cosmic origin. It was soon established that traces of the known radioactive elements were widely dispersed throughout the lithosphere and that few raw substances or even few metals were free of radioactivity in trace amounts. Man, it appeared, lived in a radioactive world and eventually it was to be found that, like his surroundings, man himself was also radioactive. It is certain that man has been exposed to ionizing radiations throughout his occupancy of this planet and it seems at least likely that in geologically recent times, no very great changes have occurred in the radiation intensity of his environment.

[7] F. W. Spiers. Brit. J. Radiol., 29, 409, 1956.
[1] Delivered at the British Institute of Radiology on May 24, 1956.

During this century, however, the situation has undoubtedly changed, for man now produces ionizing radiations and artificial radioactivities in abundance and turns them to his own great technical advantage. It is possible, perhaps likely, that the increase now taking place in man's radiation background will be greater than the other possible changes which have so far occurred, when for example ancestral man left his arboreal home for the cave, or later even, the Englishman entered his castle! It would seem fitting to put on record in this Institute an estimate of man's natural radiation dose, a quantity which members, by their professional activities, are bound in some measure to augment.

The radiation dose received naturally by tissues of the human body arises in two days: from external sources which include terrestrial radioactivity and cosmic rays, and from internal radioactivity acquired by the body from air, food, and water. The biological significance of this background radiation dose is properly a consideration for the biologist, but any physical analysis should be oriented to give the data required for a biological assessment. Because the background dose is in any case small compared with doses known to cause immediate somatic change, long-term genetic and carcinogenic actions may be presumed to be the likely considerations. The radioactivity data will be used, therefore, to derive the dose to human gonads, and the dose to osteocytes in bone. The dose to soft tissues in the body will not differ greatlyy from that of the gonads, with the exception of lung tissue where recent work by Hultqvist (1956) will be used to indicate the possible lung dose from the inhalation of radon, thoron, and their decay products. Because α rays and β rays are so easily absorbed, even by the elements of low atomic number comprising soft tissues, the dose to the gonads from external sources may be considered to be due entirely to cosmic rays and γ rays. The dose from internally acquired radioactivity, however, arises to a large extent from β rays and, when present, from α rays.

RADIOACTIVITY IN MAN'S ENVIRONMENT

1. Surface rocks and oceans

The radio-elements which contribute significantly to the terrestrial γ radiation are the members of the U and Th series together with the naturally occurring radioactive isotope of potassium, ^{40}K. The actinium series, ^{87}Rb, ^{147}Sm, ^{14}C and a number of radioactive isotopes, found in recent years to occur naturally, do not contribute significantly to the γ-ray background, either because of the character of their energy emission, or because they are insufficiently abundant. The radioactive constituents of some rocks listed in Table I show that for an "average" granite the γ-ray emission is contributed in roughly similar degree by the elements of the uranium and thorium series and by potassium 40. Sedimentary rocks are considerably less radioactive than granite with limestone least of those listed. The alum shale is given as an example of an exceptionally high rock radioactivity in Sweden, its excess activity being due entirely to its very high uranium content. Sea water has a low content both of uranium and potassium and furthermore exhibits a very low γ-ray equivalent radioactivity because, in deep water, the thorium isotopes, including ionium (^{230}Th), the precursor of ^{226}Ra, are almost completely removed by sedimentation following adsorption on ferric and manganic hydroxide while the uranium remains largely in solution (Rankama, 1954). The equivalent radium content of sea water is about 100 times lower, and river water some 10,000 times lower, than that of sedimentary rocks.

TABLE I.—*Radioactivity in rocks and water*[1]

Material	Radio-elements per g	γ-ray equivalent g Ra per g$\times 10^{12}$	
		Components	Total
Granite (average)	U: 4 μg Th: 13 μg K: 30 mg	1·44 2·25 2·40	6·1
Granite (alps)			12·4
Clays (Yorkshire)			4·4
Sandstone (Yorkshire)			2·0
Limestone			1·4
Brick			5
Alum shales (Sweden)	U: 170 μg Th: 1·5 μg K: 35 mg	60 0·3 2·8	63
Sea water	U: $1\cdot3\times10^{-9}$ g K: 0·35 mg	7×10^{-5} 28×10^{-3}	$2\cdot8\times10^{-2}$
Thames			$\sim10^{-4}$

2. *Air*

The radon and thoron contents of air (Table II) depend on the escape of these gases from the ground and on the prevailing atmospheric conditions; stagnant and dusty air will retain the gases and their decay products, wind and rain will clear the air of radioactivity. The low value over oceans reflects the low concentration of the parent elements radium and thorium in sea water.

The value of 3×10^{13} c/l is often taken as representative of the radon content of air although values ten times higher have been reported by Anderson, Mayneord and Turner (1954) on some days in central London. The radon and thoron levels in houses depend very much on ventilation as well as on the building materials used.

3. *Drinking water and foods*

Table III lists values of the radium content in some drinking waters and foods according to some recent measurements by Hursh (1956) and Muth (1956). The radioactivity of tap water depends to a considerable extent on the purifying processes, being reduced by large factors where precipitation methods are used. High radioactivity is found in mineral waters and can occur in rural areas where water is taken from wells. Some values for the radium content of foods are given although no large survey of foods has so far been undertaken.

RADIOACTIVITY OF THE HUMAN BODY

Only in comparatively recent years has attention been given to the determination of the natural radioactivity of the body. Values of the total body radium content as high as 7.5 to 14×10^{9} g Ra, reported by Rajewsky (1941) and by Krebs (1942), have not been found in modern measurements of radium in cremation ashes. The recently obtained values given in Tables IV, varying from 0.05 to 0.32×10^{9} g Ra, show reasonable agreement between measurements made by different methods in different parts of the world. There is only a slight correlation of radium content and drinking-water activity and it seems likely that, as the data in Table III suggest, the major route for radium intake is through the radium content of food. The radium contents of soft tissues have been reported so far only by Muth (1956) and are included only tentatively, in order to assess the significance of the figure for the testis in a later calculation of the gonad dose.

TABLE III.—*Radioactivity in water and foods* [1]

Source	*Radium content 10^{16} g per g*
Drinking waters:	
London	<1
America:	
Cities	0·1 to 1·4
Rural areas	0·3 to 23
Germany:	
City	1·4 to 3·1
Mineral waters	130 to 240
Thermal springs	~1100
Foods:	
Milk	0·04 to 2·7
Cereals	10 to 39
Potatoes	67 to 125
Meat	80

TABLE IV.—*Radioactivity of the body* [1]

Radio-element	Ra in tap water g/c.c. 10^{16}	Body radioactivity in in $c\times10^{9}$
Potassium 40		13
Carbon 14		87
Radium (1)	0·01	0·047
(2)	0·36	0·12
(3)		0·14
(4)	1·4 to 3·1	0·32
(5)	34	0·24
Radium in bone		10^{14} gRa/g
Radium in soft tissues		1·4 to $4·6\times10^{15}$
Radium in tests		$0·6\times10^{15}$

[1] Data mainly from Hursh (1956) and Muth (1956).

The highest radioactivity in the body expressed as curies is that due to ^{14}C, the amount in Table IV being calculated from the measured specific activity of carbon of biological origin, given by Anderson and Libby (1951) as 15.3 dis min g C. The β-ray energy of ^{14}C is so low (54 kc V), however, that the dose rate to body tissues from ^{14}C is almost negligible compared with that from potassium and radium.

The potassium content of the body is now reasonably well established, at about 0.2 percent of body weight, by measurements of body γ-ray emission by Sievert (1955), Burch and Spiers (1953), and Rundo (1955). Males show higher values than females but the differences are related to the fat content of the body which contains no potassium. Anderson (1956) has shown that γ-ray measurements of total body potassium correlate well with lean body mass, as determined by measurements of body water by the tritium method.

THE EXTERNAL RADIATION BACKGROUND

1. Local γ-radiation

In most circumstances the local rock radioactivity is responsible for the major part of the external radiation background. Calculations of the dose-rate over different types of rock have been made by Libby (1955) and by Hultqvist (1956) and estimates, based on formulae given by the latter, are shown in Table V for the surface radioactivities listed in Table I. The dose-rates are of the same order as those given by Libby and accord with such direct observations as have so far been made.

The dose-rates inside houses and buildings are greater than the corresponding open-air values because the building materials are disposed to give a nearly isotropic irradiation. Some measurements reported by Sievert and Hultqvist (1952) and by Hultqvist (1956) in open-air and in houses in Sweden are summarized in Table VI, where the original values in ions per second have been corrected for the cosmic ray component and then converted to dose-rates in mrad/year. The values given are the means of observations in some 1500 apartments and houses; in each class of building dose-rates were found, exceptionally, up to twice the mean. Measurements made recently in Leeds and Aberdeen (Spiers and Griffith, 1956) are given in Table VII where the observations fall into two groups, those in granite buildings in Aberdeen and those in brick or concrete buildings in both cities. The dose-rates are lower than those reported by Sievert and Hultqvist but, with the exception of the Swedish alum-shale buildings, the difference for brick dwellings in the two countries are not very great. Open-air dose-rates in Leeds and over clay and in wooden houses in Sweden are about the same and only about half the dose-rates in brick dwellings.

TABLE V.—*Calculated dose-rates over flat ground*

Situation	*Local γ-ray dose-rate (mrad/year)*
Granite (average)	95
Granite (alps)	228
Clays (Yorkshire)	82
Sandstone (Yorkshire)	37
Limestone	26
Alum shales (Sweden)	1150
Sea	0. 5
Thames	0. 001

TABLE VI.—*Measured dose-rates in Swedish houses*

Building material	*γ-ray dose-rate at room centre (mrad/year)*
Wood	50
Brick	104
Concrete with alum-shale	171
Stockholm streets	85
Over igneous rocks	60 to 120
Over clay	50

2. Cosmic radiation

The dose-rate given by Libby (1955) for cosmic radiation is 35 mrad/year and appears to be based on an ionization intensity at sea level of approximately 2.5 ion pairs/c.c/sec. Recent work by Burch (1954) on the interpretation of high-pressure ionization chamber measurements supports the analysis given by Clay and his colleagues (1938) and leads to a lower value of the cosmic radiation ionization. The mean of three values given by these workers, corrected to ionization in free air, is 1.92 ions/c.c./sec. which converts to a dose-rate of 28 mrad/year at sea level and geomagnetic latitudes above 41° N.

This dose-rate applies to all bodily tissues. It may, however, be some 20 percent less in the basements of tall buildings which absorb the soft cosmic ray component and it will increase rapidly with altitude. At 10,000 and 15,000 feet the cosmic ray ionization is known to increase to about three and six times the sea-level rate; but because cosmic radiation is responsible for only a fraction of the total background dose-rate, the total tissue dose-rates are increased only by factors of the order of 1.6 and 2.3 respectively.

It is possible that greater significance attaches to the increase in the heavy particle component of cosmic radiation with altitude, thereby changing the relative biological efficiency (R. B. E.) of the radiation for some biological actions. Some mutations, for example, are reported as being less effectively produced by heavily ionizing particles than by X-rays; on the other hand, in a few cases the R. B. E. for heavy particles has been reported to be in the region of 5. At sea level, however, the contribution to the total ionization by slow particles and the effect of an associated increase in R. B. E. for this component would appear to be unimportant.

TABLE VII.—*Measured dose-rates from local radioactivity*

Type of building	Location	Local γ-ray dose-rate [1]
		mrad/year
1. All granite	(a) Aberdeen—laboratory	107
	(b) Aberdeen—in bell tower	99
	(c) Aberdeen—entrance hall	101
2. Brick or concrete	(a) Aberdeen, rooms on various floors	73
	(b) Leeds, room in hospital building	81
	(c) Leeds, single storey laboratory	80
	(d) Leeds, various rooms in house	77
3. Out-of-doors	Leeds, in garden of house 2(d)	48

[1] Mean values given for centres of rooms and at 1 m above floor.

3. Atmospheric radioactivity

Radiation from the decay products of radon in the air can add to the external γ-ray dose, although the effect may be expected to be small and very dependent upon atmospheric conditions which determine the degree of radioactive equilibrium. Peirson and Franklin (1951) have calculated that at ground level an atmospheric radon content of 3×10^{-13} c/l produces a γ-ray flux of the order of 10 quanta/cm^2/min. Taking a mean energy for Ra B and C γ rays, the tissue dose rate for this flux is 2.2 mrad/year. The formula used by Hultqvist (1956), which includes a factor for scattered quanta, gives a dose-rate, for the same radon level, of approximately 4 mrad/year and this figure will be used in subsequent calculations. Under most conditions this contribution to the background dose-rate is trivial but for the higher levels of atmospheric radon given in Table II (or for the higest value, 2 to 3×10^{-12} c/l., reported by Anderson, Mayneord and Turner, 1954, for London air), the γ-ray dose could be of the same order as that due to cosmis rays.

Calculations of dose-rates due to thoron in air lead to values of the same order of magnitude as those for similar levels of radon activity. The dose-rates for the thoron levels given in Table II are from 0.6 to 2 mrad/year. Apart from Hultqvist's data for Swedish houses, however, no information is available on the general level of thoron in air and no allowance for thoron has been included in the subsequent tabulation of dose-rates.

THE INTERNAL RADIATION BACKGROUND

1. Potassium.

The potassium content of the body provides the chief source of internal radiation to soft tissues. Taking the average tissue content of potassium to be 0.2 per cent and using Sawyer and Wiedenbeck's (1950) constants for the radioactivity of ^{40}K as 28.3 β particles per second per g K of mean energy 0.605 MeV and 3.6 γ quanta per second per g K of energy 1.46 MeV, the tissue dose can be calculated to be:

Tissue dose rate due to K=18 (β)+2 (γ)=20 mrad/year.

Because the mean range of the β particles of ^{40}K is only some 2 mm in tissue the dose-rate in a given organ is determined mainly by its own potassium content. With regard to the gonad dose, flamephotometer measurements on testes and ovaries taken from two post-mortem examinations gave a mean potassium content of 0.20±0.02 per cent. Although observations have been made so far on only four specimens, the results suggest that the mean content assumed in the ^{40}K calculation is sufficiently representative of gonad tissue.

2. Carbon 14

The specific activity of ^{14}C in carbon of biological origin is 15.3 β particles/min/g C (Anderson and Libby, 1951) with a mean β-ray energy of 0.15 MeV. Taking the carbon content of tissue as 18 per cent, the energy deposition due to ^{14}C amounts to a tissue dose-rate of only 1 mrad/year.

3. Radon and its disintegration products in air

An estimation of tissue dose arising from the inhalation of air containing radon can be made if, in the absence of complete information on all the factors concerned, some simplifying assumptions are made. The concentration of radon in the atmosphere is regarded as uniform and it is assumed that the breakdown products (RaA, RaB, RaC and RaC′) are in equilibrium with the radon and are uniformly suspended in the air, a condition holding probably only in still air. The calculation is then made in two parts: (1) for a steady level of radon (plus disintegration products) in body tissues *via* the blood in contact with the radon in alveolar air, and (2) for a steady intake into the lungs of the disintegration products formed in the external air.

The solubility of radon in water at 37° C. is 0.17 and in fat the figure is about five times higher. If the concentration of pure radon in alveolar air is R, the concentration of radon in the 50 kg of aqueous tissue will be 0.17R and that in the 10 kg of fatty tissue will be 0.85 R, giving a mean for the whole soft tissues of 0.27 R. This level of radon in the tissues is maintained and hence it will maintain its disintegration products in equilibrium with it. Taking the effective disintegration energy of the series Rn RaA . . . RaC′ as MeV and assuming an atmospheric radon content of 3×10^{-13} c/l, the energy deposition per gram of tissue corresponds to a dose rate of only 0.03 mrad/year, mainly from α radiation. Using an R.B.E. of 10, to enable α-ray dose-rate to be added to the β and γ-ray dose-rates already calculated, the mean tissue dose-rate for the dissolved radon is 0.3 mrad/year.

If the disintegration products are present in equilibrium with the radon content of the air, these are also swept into the lungs by the inspired air and, where they are deposited, build up an equilibrium level which is determined by the inspiration rate. Following the recommendations of the International Commission on Radiological Protection, the distribution of the inhaled products will be taken to be: 25 per cent exhaled, 50 per cent retained in the upper respiratory passages and subsequently swallowed and 25 per cent deposited in the lungs. Because of the short half-lives of the decay products RaA . . . RaC′ and their low transference from the gut to the bloodstream, the fraction of the products swallowed will contribute little to general body dosage. This fraction, however, would irradiate the areas in the upper respiratory tract where the deposition was initially localised. In the case of soluble compounds, all the fraction deposited in the lungs would be taken up by body fluids; in other cases perhaps half the lung deposition would be generally disseminated. It would probably be safe to assume that some 20 per cent of the inhaled disintegration products could give rise to the irradiation of the general body tissues.[a]

For the atmospheric radon content assumed and an inhalation rate of 20 m^3/day the dose-rate to soft tissues from inhaled decay products is 0.16 mrad/year or 1.6 mrem/year. The total dose-rate to the general soft tissues of the body from inhalation of air containing 3×10^{-13} c/l, of radon and disintegration products might amount, therefore, to about 2 mrem/year, a quantity which remains small compared with other dose-rates, but one which might become significant under conditions of high atmospheric radioactivity.

[a] It can be shown that for an influx of K c/sec. of the disintegration products RaA . . . RaC′, the energy dissipated per second at equilibrium will be:

$$\Sigma(E)=3{\cdot}7\times10^{10}K\left\{E_A\left(\frac{1}{\lambda_A}\right)+E_B\left(\frac{1}{\lambda_A}+\frac{1}{\lambda_B}\right)+E_C\left(\frac{1}{\lambda_A}+\frac{1}{\lambda_B}+\frac{1}{\lambda_C}\right)+E_{C'}\left(\frac{1}{\lambda_A}+\frac{1}{\lambda_B}+\frac{1}{\lambda_C}+\frac{1}{\lambda_{C'}}\right)\right\}$$

MeV/sec where E and λ are respectively the particle energy in MeV and the transformation constant in sec. $^{-1}$.

TOTAL DOSE-RATE TO GONADS

In summarising the total gonad dose from all sources it is necessary to allow for the shielding of the gonads by overlying body tissues. The shielding factors, which reduce the dose from the local γ radiation, have been determined by using a water-filled tin model in which measurements of the normal background intensity could be made at the sites of the ovary and testis. The screeing factors were derived from the measurements after appropriate corrections had been made to allow for the cosmic-ray contribution to the instrument response. In the female, the loyal γ radiation was found to be reduced by factors of 0.52 to 0.59 depending on the position adopted by the model. In the male the screening factors varied from 0.67 to 0.72 and a mean factor of 0.63 was derived as the average for both sexes. This factor, which is unlikely to be in error by as much as $\pm$ 10 per cent is applied to all estimations of gonad dose from local γ radiation.

Table VIII summarises the dose-rates which may be regarded as typical for regions of this country, and possibly elsewhere, where the local rock radioactivity is not specially high and the buildings are of brick or concrete not incorporating highly radioactive materials. An arbitrary division of the day has been made by assuming six hours of the 24 to be spent out-of-doors.[3] Possible small additions to the total dose-rate would be not more than 2–3 mrem/year for thoron in air and 1 mrem/year for the radium content of the testis suggested by Muth's (1956) data.

Table IX illustrates the range of dose-rates deduced for various situations in this country and in Sweden. Greater differences between localities could be obtained by taking the extreme values observed in some of the Swedish and other sites, but as far as possible an attempt has been made to assess the conditions affecting large numbers of people. Thus because even agricultural workers spend some eight hours in a brick house their radiation dose is not very different from that calculated for a town dweller in the same geological area. The body shielding factor considerably reduces the differences otherwise apparent in situations of differing local radioactivity.

TABLE VIII

Radiation source	*Dose to gonads per year*
External irradiation	
Cosmic rays (sea level)	28 mrad
Local γ rays (Leeds, 78 mrad year indoors, 48 mrad/year out-of-doors)	45
Radon in air, $3 \cdot 10^{13}$ c/l	1
Internal irradiation	
Potassium 40	20
Carbon 14	1
Radom dis. products, $3 \cdot 10^{13}$ c/l	2
Total dose per year	97 mrad [1]
Dose to age 30 years	2·91 rad [1]

[1] Includes allowance for the R. B. E. of the α radiation, where present, and therefore also expresses the gonad dose in rem.

TABLE IX.—*Gonad doses*

Location and buildings	*Dose rate mrad/year*
Leeds, brick:-	
(1) outdoor worker	90
(2) indoor worker	97
Aberdeen, granite	113
Stockholm:	
(1) wood	89
(2) brick	114
(3) concrete	146
At 15,000 ft. on granite:	
(1)	244
(2)	328

[3] The assumed time out-of-doors, which is used illustratively, is probably above average for city dwellers.

The last two entries illustrate the overall effect of the sixfold increase in cosmic-ray ionization at an altitude of 15,000 feet in a situation where the rock is granite, as for example in the Andes. Two granites have been chosen (as in Table I) and the resulting dose-rates are respectively 2·2 and 1·7 times the corresponding values over the same rock at sea level.

DOSE TO LUNGS

In addition to dosage from external sources of radiation and from ^{40}K, lung tissues will receive further irradiation from inhaled particulate matter carrying the decay products of radon and thorium. Some of this radioactivity will lodge in the upper respiratory tract and be removed in perhaps a matter of hours by ciliary action. In this time, however, irradiation will have occurred from the short-lived radon product RaA. Radioactivity on the finer dust particles ($< 1\ \mu$) will enter more deeply into the lung tissues *via* the alveoli and, unless rapidly dissolved, will produce a general irradiation of the lung tissues.

Chamberlain and Dyson (1955) and Shapiro and Bale (1953) have considered the problem of dose to the trachea and bronchi and have come to approximately the same conclusion as to the order of magnitude of the dose produced by a given atmospheric radon content. Chamberlain and Dyson have shown that for a radon concentration in air of 3×10^{-13} c/l., bronchial tissues to a depth of 45 μ (the range of the RaA α particles) receive an average dose-rate of 220 mrem/year. The total dose-rate from all sources would then be of the order of 315 mrem/year. The total dose-rate from all sources would then be of the order of 315 mrem/year to the superficial bronchial tissues, a rate about three times that calculated for the general soft tissues of the body.

If it is assumed that the 25 per cent of decay products reaching the alveoli are insoluble and remain in the lungs, calculations similar to those given in an earlier section show that the average lung dose would be about 160 mrem/year for an air activity of 3×10^{-13} c/l. A very comprehensive analysis of problem of lung dosage from both radon and thoron decay products has been given by Hultqvist (1956). The dose-rate to lung tissue due to a radon concentration of 3×10^{-13} c/l. can be deduced from Hultqvist's results as 150 mrem/year. The thoron concentrations given by Hultqvist (see Table II) are about ten times lower than the radon levels and, assuming a thoron concentration of 3×10^{-14} c/l., the resulting lung dose according to Hultqvist could be about 200 mrem/year. The total lung dose from all sources would then be about 245 mrem/year if the radon only is included and 445 mrem/year including radon and thoron. A high ventilation rate (3·5 changes of the air per hour) reduces the radon and thoron doses by a factor of nearly 4, in which case the lung dose from all sources would be reduced from 445 to 190 mrem/year. It appears, therefore, that the dose-rate to lung tissue may be from two to four times that received by other body tissues when the radon and thoron concentrations in air are respectively 3×10^{-13} c/l. and 3×10^{-14} c/l.

DOSAGE IN BONE

The bone tissues likely to receive the highest dose from natural sources are the osteocytes lying in regions of bone which incorporate radium. An average dose to an osteocyte of a given size can be deduced from the radium content of the body on the assumption of uniform radium deposition. In those cases of radium poisoning which have been studied by autoradiography (especially by α-particle track photographs) the radium occurs in localised areas where the dose-rate has been shown to be as much as 10 to 20 times the average. Nevertheless, the calculation of an average dose-rate will be a satisfactory measure of the general background irradiation of bone and will serve as a means of assessing the significance of the ingestion of bone-seeking radioactive isotopes.

The dose-rate to osteocytes from sources external to the bone will be practically the same as in the calculations for soft tissues, but the potassium contribution to the dose-rate will be less because its concentration in bone is about four times less than in muscle. The resulting dose-rate from sources other than radium can them be put at about 82 mrem/year (Table X).

TABLE X.—*Background dose-rates to bone*

Conditions	Radium in skeleton	Dose rates to osteocytes in mrem/year		
		Radium	External sources	Total
Not specially radioactive region Radon in air 3×10^{-13} c/l.	10^{-10} g	39	82	121

The radium body burdens listed in Table IV suggest that for a region not specially radioactive a representative value for the radium content of the skeleton might be 10^{-10}g Ra. Using methods of calculation similar to those given by Spiers (1953) the mean dose-rate to an osteocyte of diameter 5μ would then be 39 mrem/year, making a total from all sources of 121 mrem/year. The extent to which this might vary from site to site in bone connot be estimated with any confidence because the deposition of radium in the skeleton due to a low continuous intake has not so far been studied.

ACQUIRED RADIOACTIVITY TO PRODUCE THE EQUIVALENT OF THE BACKGROUND DOSE-RATES

At a time when the accidental ingestion of radioactive materials must be regarded as at least a possible accompaniment of nuclear energy development, it is of interest to consider what quantities of acquired radioactive elements will produce dose rates equal to those already being received by body tissues from natural sources. Two fission products would seem to be particularly important in that they are long lived and are capable of being taken into the body structure. Radioactive caesium, ^{137}Cs, may be expected to follow potassium in its behaviour and distribution and strontium 90 is known to be taken up in bone.

In the case of ^{137}Cs, which emits β rays of 0.55 MeV and 1.21 MEV energy and a γ ray of 0.66 MeV, a body burden of 0.6 μc is required to give the soft tissues of the body a dose-rate equal to the background rate of 100 mrem/year. This comparative figure is relevant to any discussion of the significance of an acquired ^{137}Cs activity.

In the case of ^{90}Sr with its radioactive decay product ^{90}Y, a body burden of 45×10^{-9} c would result in an average dose-rate to osteocytes equal to that received from natural sources including a radium burden of 10^{-10} g. If, however, it is conceded that the concentrations of strontium in bone can be five times higher than those observed with radium (I. C. R. P. 1953), the introduction of this further factor of 5 reduces the amount of ^{90}Sr+^{90}Y equivalent to the background radioactivity to 9×10^{-9} c. Assuming the calcium content of the skeleton to be 1000 g, the ^{90}Sr contents can be expressed respectively at 45×10^{-12} and 9×10^{-12} c of ^{90}Sr per g Ca.

DISCUSSION

The importance of an estimate of the dose-rate from natural radiation lies in the fact that it is the inevitable accompaniment to life and has been so throughout man's evolution. It must form one basic element of comparison in any judgment of what is a tolerable level of human dosage from the new radiation sources. It would seem that the natural dose-rate, if not an essential factor in man's environment must be at least a tolerable one. Furthermore, a comparison of the natural background dose-rate with dose-rates known to be harmful will give some indication of the range within which "permissible" rates must be set—although it is beyond the proper scope of this discussion to consider what those rates should be.

In relation to genetic effects, comparison must be made with the dose received by the gonads from background radiations. It seems likely that this dose-rate is not far from 0.1 rad per year or 3 rad in a generation time of 30 years, and that, even in houses incorporating highly radioactive shales in their structure, the dose level is not much more than 50 per cent greater than this. Although reservation is necessary, in view of the paucity of information, great variations in the background dose-rates to large populations seem rather unlikely, because local γ radiation provides only part of the background dose and its contribution to the gonad dose is reduced by the shielding of overlying tissues.

The relationship of a gonad dose of 3 r in a generation to that required to double the human spontaneous mutation rate is uncertain because the radiosensitivity of human genes is unknown. The most recent estimate that can be quoted is that of Muller (1955) which suggests that the so-called doubling dose is unlikely to be much more than ten times this background dose.

The dose-rate to the soft tissues in bone is only slightly in excess of that to the gonads because the contribution from the small natural radium content of the skeleton is partly off-set by a reduced contribution from potassium. A dose-rate of about 0.12 rad per year or about 6 rad in 50 years appears to be a reasonable estimate. This is some 2000 times less than dose-rate to osteocytes which have been estimated in cases where small accidental radium burdens (of about 0.4 μg) have ben associated with radiographically detectable but not necessarily malignant—changes in bone.

It has been shown that the dose rates from natural sources to the upper respiratory tract and to the general tissues of the lung may be as much as three times the gonad dose-rate for an assumed normal atmospheric radon content of 3×10^{-13} c/1. The dose in 50 years, 15 rad, is from 100 to 1,000 times less than the order of dose estimated in cases where the occurrence of cancer has been associated causally with the irradiation of body tissues. It is probably 10,000 times less than the lung dosage in the uranium miners of Joachimstal amongst whom the incidence of lung cancer was so marked.

It is evident, therefore, that the natural background dose stands nearest in relationship to those doses thought to be genetically significant. Several orders of magnitude lie between the natural dose and those associated with carcinogenesis. Clearly in any assessment of the significance of population dosage, these differences of magnitude must be recognized and taken into account.

BIOLOGICAL EFFECTS OF RADIATION

An open meeting was held on March 7 at the Institute of Biology under the titl "Aspects of Radiotoxicity," with the aim of clarifying some of the problems arising from the increasing level of radiation. Dr. H. O. J. Collier, in the chair,

set the evening's challenging tone to the scientist by opening the discussion with the quotation, "Man, proud man, drest in a little brief authority, . . . plays such fantastic tricks before high heaven, as make the angels weep". This challenge was taken up by Prof. J. Rotblat, who spoke on the physical aspects of radiation damage, and by Prof. L. Penrose, a member of the Medical Research Council Committee (1956) for the study of radiation hazards, who discussed biological damage, including the genetic effects.

Prof. Rotblat began by stressing the complexity of the problem. On the physical aspect alone, and confining the discussion to ionizing radiations, there is a multitude of particles to consider, from electrons to fission fragments, with widely differing energies, penetrating powers and types of secondary reactions produced. Compared, however, with the chemical, biochemical and biological processes contributing to radiation damage, the nature of which is still obscure the physics of radiation damage is fairly well understood. The passage of radiations through matter gives rise to excitation and ionization of atoms and dissociation of molecules. All these contribute to the biological action and for this reason it is necessary to consider the total energy transferred to matter rather than ionization alone. The unit employed is the linear energy transfer (sometimes referred to as the L. E. T.), which is the amount of energy transferred per unit length of path of the ionizing particles, usually measured in keV. per micron of tissue. This does not depend on the mass of the ionizing particle but only on its charge and velocity. The very marked variation with velocity explains the observed difference between the damaging action of alpha particles, protons and electrons, of the same energy. But although different particles with the same value for the linear energy transfer produce the same biological effect, the relationship between the linear energy transfer and biological damage, or the relative biological effectiveness (R. B. E.), is not at all straight-forward. Prof. Rotblat quoted examples of biological processes, in some of which the biological damage increases with linear energy transfer, in others decreases with it, and in still others first increases and then decreases. These variations indicate the existence of different mechanisms of biological action.

Turning to the doses of ionizing radiations to which man is nowadays exposed, Prof. Rotblat made a survey of the natural background of radiation, pointing out that this will differ depending on whether one considers the gonad dose, the dose to bone or to other tissue. In Great Britain the gonad dose is 0·1 r. per year, or 3 r. in thirty years; the bone dose is slightly greater and amounts to 8·5 r. during seventy years of life. Of the man-made radiations, the largest contribution is from diagnostic radiological examination. The Medical Research Council report gave a figure of 22 per cent of the natural background, but more recent evidence indicates that the actual value may be 5–10 times higher, which would bring it in line with that in the United States. The fall-out from nuclear test explosions has up to now contributed very little so far as external radiations are concerned, but internal radiation gives rise to some concern. The effect of cæsium-137 in the body, although quite small, has perhaps been dismissed too lightly, but the concentration of strontium-90 in bone is the more worrying factor.

All these doses appear quite safe when compared with the maximum permissible dose (M. P. D.) established by the International Commission on Radiological Protection, which amounts to 0·3 r. per week, or 150 times the natural background. It has, however, to be remembered that the maximum permissible dose was set up for people occupationally exposed, and on the assumption that only a small fraction of the population is so exposed. For the whole population the figure may have to be reduced by a factor of 10 or even 50, but there may be other reasons for lowering the maximum permissible dose. It is now becoming evident that the doubling dose of leukæmia may be much less than was thought. Another factor, which came to light only recently, is the shortening of life-span due to an acceleration of the natural processes of ageing. A survey of radiologists in the United States, showing a reduction of life-span by five years, may be statistically uncertain, but there is no doubt about this effect from experiments on animals. These experiments show that every irradiation results in some irreparable damage, and that the lethal dose gradually decreases with age. If this is extrapolated to human beings, it leads to an inherent limit of life-span due to the natural background of radiations. This limit may be two hundred years or more, but the grim significance of this sort of speculation becomes apparent when applied to the present maximum permissible dose, which would reduce the life-span to about thirty years from the time exposure began. There seems, therefore, to be a good case for lowering the maximum permissible dose, quite apart from the genetic hazards.

Prof. Penrose opened his discussion of the biological damage due to radiations by directing attention to the ignorance there is of the intermediate steps in their action, stating that one could only speculate with the knowledge available. He pointed out that the major damage to populations exposed to an atomic explosion would be due to heat and blast, and not to radiation. Ionizing radiations were, however, damaging even in small intensities. Their effects could be divided into immediate, during the first few weeks, and delayed. The immediate effects, such as burns and anæmia, are well known. Their relation to the dose received is not linear, lower doses producing apparently no effect. With the delayed effects, such as cataract or leukæmia, the picture is different. From the evidence on survivors at Hiroshima and Nagasaki, as well as from the findings of Court Brown and Doll on patients treated with X-rays for anklyosing spondylitis, it is clear that the incidence of leukemia increases linearly with the dose. This linear relationship between exposure and delayed effects emerged toward the end of the Medical Research Council Committee's deliberations and was the reason for the demand for a reconsideration of the maximum permissible levels.

Another point to be clarified in the public mind is the difference between somatic and genetic effects. Direct damage to the fœtus by radiations has been studied on pregnant rats and mice as far back as 1931, and the findings have been supported by observations on human fœtuses. It was found that large doses to the mother's abdomen could clearly cause fœtal damage not previously suspected. Apart from miscarriage, this could result in the birth of babies with arrested development of the central nervous system leading to a special type of microcephaly. These risks, which had been known for some time, were definitely confirmed in the populations exposed at Hiroshima. Dr. Alice Stewart and her colleagues at Oxford claim to have observed delayed deleterious effects on the fœtuses exposed at any time during pregnancy to a much smaller dose of X-rays, such as occurs during diagnostic pelvic X-ray of the mother. In these offspring there was found to be a significantly higher incidence of leukæmia, which developed one, six, or even ten years after birth. Prof. Penrose hesitated to accept these findings as fully proved, but felt that although the damage occurred only in a small proportion of the mothers X-rayed in pregnancy, nevertheless it was important.

The genetic hazard can only be considered by looking at a long-term picture. There are two processes to be considered—chromosome breakage, which disturbs nuclear harmony, and point mutations, both of which may be the result of ionizing radiations. When a chromosome breakage occurs, both theory and experiment show that the effect is proportional to the square of the dose because, to produce an effect, there must be two breakages with the possibility of joining up again to reproduce. In the case of point mutations there is a direct linear effect, and this has been established by work with *Drosophila*. In man, such mutations are far from difficult to study, and this has in part produced the impression that the genetic hazard results only in an increase in the number of achondroplasic dwarfs. Actually, an increase in the rate of mutations will increase many other far more serious conditions. Referring to the nuclear test explosions, Prof. Penrose stated that the number of fresh mutants would be small and difficult to demonstrate, and in this sense only is it insignificant, counted over the whole population the number would certainly not be negligible.

Prof. Penrose then produced some evidence of the part played by radiation on the natural mutation-rate in man. One method is to study the incidence of diseases believed to arise by spontaneous mutation in relation to the ages of parents. For chondrodystrophy and acrocephalosyndactyly the age of the father, but not that of the mother, is strikingly high. This could be explained by assuming that the gene loci concerned were not very sensitive to radiation but mutated in response to other factors. For the most sensitive loci, mother's and father's age would both be only slightly raised, as seems to be the case in retinoblastoma neurofibromatosis and epiloia. Mongolism falls into a quite different group, its incidence increasing with an increasing maternal, but not paternal, age, and it is clearly not due to point mutation.

In answer to questions on the haphazard use of radioisotopes therapeutically and experimentally, both speakers stressed that nowadays every care is taken in the use of these materials. Prof. Rotblat explained that in the case of radioiodine therapy in thyroid disease, treatment is now limited to patients of the older age group where tumour induction after many years is of less importance

than in the younger age group. Physicians in Britain have been more conservative in accepting the possession of a Geiger counter as essential for their practice than has the medical profession in the United States. The contribution from short-lived isotopes used in medicine has been calculated to be very small.

The chairman concluded the meeting by a revision of the old rules of health, suggesting that one should stay indoors to be shielded from cosmic rays, to stop drinking milk to limit the intake of cæsium 137, and to keep away from the doctor, to avoid being X-rayed.

STRONTIUM-90 IN MAN

Whenever a nuclear weapon is exploded, or atomic energy is released in a reactor, over 200 radioactive isotopes are produced. All these can be harmful to man, but the main villain of the piece appears to be strontium-90. Its notoriety is due to several reasons. First, it has a high yield: one in every twenty fissions results in the production of an atom of strontium-90. Secondly, it is long-lived: its physical half-life is 28 years. Thirdly, it finds its way from the soil into food. Fourthly, it is a bone seeker. And, fifthly, it is retained in the human body for a long time; the biological half-life is about 7½ years. The last two properties lead to the possibility that the β-rays emitted from radiostrontium may produce bone lesions and sarcomas as well as leukaemias.

Although the hazards from the deposition of strontium in bone have long been recognized, too little has been known about its distribution and metabolism to assess the hazards quantitatively. Recent papers [1,2,3] giving results of a world-wide survey of strontium content in man throw some light on the subject. Strontium-90 is an inevitable by-product of nuclear power production, and by the time most of our power requirements have been met from atomic energy there will be an embarrassingly large quantity of strontium-90 to be disposed of; but this does not present a hazard at the moment, since the strontium is not allowed to escape into the open. Even in a full-scale nuclear war strontium-90 would not be the main radiological poison; its damaging action would be small compared with that of the shorter-lived isotopes strontium-89 and iodine-131. It is the relatively small amount of strontium-90 accumulating from test explosions that causes some worry. Furthermore, strontium-90 does not present a genetic hazard, since it emits only β-rays, which do not penetrate to the gonads. It is the somatic hazard, the probability of inducing bone tumours, that is the main concern.

When a nuclear weapon is exploded in the air the radioactive fragments are carried by the upward draught high into the stratosphere. In the case of a high-altitude explosion—as the next British H-bomb test is supposed to be—there is very little local fall-out, and practically all the radioactivity is taken up into the stratosphere. The rate of descent from there is very low, about 10% per year, and this allows the radioactivity to spread out over the globe, so that when it does come down, mainly with the rain, it is nearly uniformly distributed all over the world. By the time the active material has descended the short-lived radioactive elements have practically all decayed and only the long-lived ones, mainly strontium-90 and caesium-137, are deposited on the ground. Here strontium, being chemically similar to calcium, enters into the soil–plant–animal–human chain of calcium. The first step in the chain, the uptake of strontium by plants, depends on the root depth and on the calcium content of the soil. The latter varies greatly; differences by a factor of 100 are quite common. Since the uptake of strontium by the soil will be the greater the less calcium it contains, the concentration of strontium-90 per gramme of calcium in the soil, and thus the concentration in plants, may vary enormously. There is also a large variation with depth, most of the strontium being deposited in the top 4 in. (10 cm.) of soil. The consumption of vegetable food is one way of introducing strontium-90 into the body. But since most of the calcium

in our diet comes from dairy products the next step in the chain, the uptake of strontium by grazing animals, is the most important one. Fortunately there is a large discrimination factor, of about 7, against strontium consumed by the cow appearing in the milk. Furthermore, there is another discrimination factor, of about 8, in going from food to the deposition of strontium in bone, so that the amount of strontium-90 per gramme of calcium in the human bone is very much smaller than that in the soil.

The concentration of strontium-90 is expressed in terms of so-called sunshine units (S. U.), one such unit being one-millionth of a microcurie per gramme of calcium. A recent survey[3] has shown that the content of strontium-90 in the human skeleton, resulting from all H-bomb tests carried out until the autumn of 1956, will eventually reach a value of about 2 S. U. This is an average value with a very wide spread. The uptake in different bones in the skeleton varies by as much as a factor of 15, the largest concentration being in the vertebrae and sternum, the lowest in the skull. There is also a big variation with age; children aged 0–4 years take up about five times more than adults, and they have also a greater sensitivity to radiations. Finally, there are large variations in individuals of the same age group, probably due to differences in diet.

The main problem is how to assess the hazard from a given amount of strontium-90 in bone. The maximum permissible concentration of strontium-90 is 1,000 S. U., which is 500 times the average amount which will accrue from test explosions. But such a comparison is misleading, since all maximum permissible levels were established for people occupationally exposed to radiations. When whole populations are exposed the maximum level must be greatly reduced. The assessment of this hazard hinges on a fundamental question: how does formation of bone tumours vary with dose? If a threshold dose exists below which tumours are not formed, then the small doses resulting from test explosions are probably harmless. But if there is no threshold, and tumour formation is a linear function of dose, then even the smallest dose will impart a small but finite probability of a bone tumour being formed. The available evidence is meagre, and, moreover, it entails comparison of strontium with raduim, since only after exposure to radium has production of bone sarcoma in man actually been observed. There is growing evidence that the relation between the amount of exposure to radiations and the probability of developing long-term effects is of a linear nature. This was the view accepted by the M. R. C. in its report,[4] which states that "each unit quantity of radiostrontium absorbed by the bone confers a certain probability of bone tumour formation." The consequence of a linear relationship is that every H-bomb test by causing an increase of the content of strontium-90 in bone will increase the frequency of bone lesions. But much more research work will be required before an accurate assessment of the hazard can be made.

Leukaemia and Natural Background Radiation

Sir,—It is now well established that ionizing radiations can cause leukaemia in man. The detailed survey carried out recently by the U. K. Medical Research Council[1] of the incidence of leukaemia among patients treated for ankylosing spondylitis with x-rays, as well as the earlier investigations by the U. S. Atomic Bomb Casualty Commission[2] of the survivors of Hiroshima and Nagasaki during the period 1947–55, have definitely shown that the incidence rate of leukaemia increases with the strength of the radiation dose received. Although the exact relationship between the two is not definitely established, it may not be unreasonable to assume—and there is some recent evidence in support[3]—that the probability of incidence of leukaemia is directly proportional to the strength of the exposure (at least for low and moderate doses).

In the analysis carried out by the U. K. Medical Research Council, the x-ray dose was estimated in two different ways—first, by calculating the total amount of energy absorbed by the whole body, and, secondly, by calculating the maximum dose of radiation received (at a point in the spinal marrow). The whole-body dose is more relevant in the present discussion.

[1] The Hazards to Man of Nuclear and Allied Radiations, 1956. H. M. S. O., London.

[2] Pathological Effects of Atomic Radiation, 1956. National Academy of Sciences, U. S. A.

[3] British Medical Journal, 1956, 2, 704.

In the table given below, the figures in the last column are calculated from the corresponding data in columns 1 and 2, which are reproduced from the U. K. Medical Research Council's report. Thus, for instance, the whole-body integral dose of 7.5–14.9 megagram-roentgens (average 11.2) would correspond to a whole-body dose of about 160 roentgens for the "standard man" (mass 70 kilograms). The leukaemia incidence rate for this dose is 4.4 cases per 10,000 men per year (if we exclude the natural rate of 0.3 cases per 10,000 per year). Thus the incidence rate per roentgen per year per million persons comes out to be 2.8.

Whole-body Integral Dose in Megagram-roentgens	Crude Incidence per 10,000 Men per year	Incidence per Million per Year per Roentgen
0	[1] 0·3	
<7·5	0·7	>0·4
7·5–14·9	4·7	2·8
15·0–22·4	5·1	1·8
22·5–37·4	11·3	2·6
37·5–52·4	22·6	3·5
>52·5	60·2	<8·0

[1] The rate has been estimated from the national vital statistics for all forms of leukaemia excluding lymphatic leukaemia.

It may be seen that the incidence rate of leukemia is roughly 3 per million per year per roentgen.

An analysis of the Japanese data leads to a figure of roughly 1 per million per year per roentgen. This represents a lower limit to the incidence rate, since the gamma-ray doses have been estimated for a person in the open. Apart from the uncertainty in estimating the dose in this case, the actual radiation dose received by the survivors must have been much less, by a factor of 2 to 3, due to shielding. Thus the incidence rate is again seen to be very roughly of the order of 3 per million per year per roentgen.

Let us assume that the natural incidence of leukemia is due entirely to the action of the background radiation (to which everyone is exposed). The average natural death rate due to leukemia is of the order of 15 per million per year. In England and Wales the annual death rate from leukemia was 11 per million in 1920, and 49 per million in 1954; the reason for this increase is not yet clear. The Japanese death rate is about 16 per million per year.) A person receives a whole-body dose of 0.1 to 0.15 roentgen per year from natural background radiation—that is, from the naturally and normally present radioactivity in his own body and the radioactivity and cosmic rays in the environment. This is equal to a dose of 3 to 5 roentgens up to adult life (say, 30 years).

On the assumption that the natural incidence of leukemia is due entirely to background radiation, the figure of 3 leukemia cases per million per year per roentgen and a natural radiation dose of 5 roentgens up to adult life would lead to a natural adult incidence rate of 15 per million per year. The close agreement between the incidence rate as calculated above and the observed rate may, no doubt, be partly accidental, but it points to the high plausibility of the assumption that the natural incidence of leukemia could be due entirely to the background radiation.

Our thanks are due to Professor D. S. Kothari and Dr. M. L. N. Sastri for stimulating discussions.—We are, etc.,

SANTOSH KUMAR MAZUMDAR.

NEW DELHI.

[Reprinted from British Medical Journal, April 20, 1957]

STRONTIUM-90 IN MAN

Sir,—Strontium-90 is now frequently being discussed all over the world, and your leading article (*Journal*, March 30, p. 752) will no doubt be quoted in lay fora as an expression of the best medical opinion of this country. It is important that some of the weaknesses of this, in most ways excellent, short summary of the situation should be noted.

"The main problem is how to assess the hazard from a given amount of strontium-90 in bone." Most would agree with this quotation.

Permissible Body Burden for the Occupationally Exposed.—This has been given by the International Commission on Radiological Protection and the Medical Research Council's Committee on Protection against Ionizing Radiation as 1 μc of strontium-90 or approximately 1,000 S. U. (strontium units, μμc per gramme of calcium), and was derived as follows. From industrial experience in the luminizing industry it was considered that the minimum toxic body burden of radium—a chemical analogue of calcium and strontium—was 1 μc. Early results with experimental rodents in Chicago had indicated that the toxic dose of strontium-89 relative to radium was about 10:1. Strontium-90 and its daughter yttrium-90 liberate per disintegration about twice the energy of strontium-89. Therefore the ratio of strontium-90 to radium should be about 5: 1 as administered; but radium decays in the body to radon, a gas, much of which escapes in expired air, more in the case of recently deposited radium than from long-standing depots, and more in the case of experimental rodents than man. In terms of body burden of effective radiactive material in human bone it was to allow a factor of 2 for this, bringing the ratio strontium-90: radium=10: 1. The calculated, minimum toxic permanent body burden for strontium-90 is thus 10 μc. Allowing a safety factor of 10 a maximum permissible body burden of 1 μc was derived.

The following uncertainties are relevant. (1) Industrial radium used in the luminizing industry was a mixture containing variable amounts of mesothorium and other radioactive elements, too short-lived for their contribution to the observed toxic manifestations to be assessed at the time when the body burdens of luminizers were estimated. However, a few subjects who had received injections of relatively pure radium for medical (*sic*) reasons have been discovered: in them the minimum toxic body burden appears so far to be about 8 μc[1] as compared with recent estimates of about half a microcurie of "radium" in ex-luminizers. The minimum toxic body burden of radium cannot therefore be indicated with precision. (2) The ratio of toxic doses of radium and strontium-89 was derived from injected animals. After more chronic administration these radioactive materials may be expected to be more widely distributed in bone. (3) The comparative metabolism of radium and strontium may differ significantly in man from the rodent because of different size and bone structure.

Permissible Body Burden in General Population.—In spite of the uncertainties the maximum permissible body burden for strontium-90 remains one of the best authenticated among those derived for occupational purposes. However, because of the uncertainties it is not justifiable to use this figure as a yardstock when one is considering a general population as Libby[2] and Kulp *et al.*[3] have done. Your leading article and the Medical Research Council[4] have given the most cogent reason—the presence in a general population of foetal, neonatal, and adolescent subjects who have greater avidity for and greater sensitivity to radioactive strontium. On the other hand, with the homoeopathic doses they receive daily the young will distribute strontium much more uniformly in bone than will the adult. How much this latter offsets the former is unknown.

This matter of distribution of strontium is worthy of stress. The values given by Kulp *et al.*[3] for strontium–90 in human skeletons were not those directly measured but figures "normalized" for unevenness of distribution in different bones. Now, unless I am in error, the factor for normalization was derived from the single administration of strontium–85 to adults in the terminal phase of killing diseases. An ill adult patient, probably bed-ridden, given a single dose of a radioactive marker and dying 3 to 125 days later, is no criterion for the metabolism of a daily ingested calcium analogue, and to use this criterion to "normalize" observed data, particularly from children, is, to say the least, unscientific. In fact field studies on domestic animals[5] indicate that gross radioactivity from strontium–90 is fairly uniformly distributed throughout the bones. Moreover, the analysis of stable strontium in human bones from subjects of all ages shows a similar uniformity.[6] Strontium is a normal though apparently

non-essential metabolite, and radioactive strontium will follow the same pathways.

Radioactive strontium–90, now universally distributed over the surface of the world, should be considered in comparison with the naturally occurring radium found in all bone, human and animal. Calculations of acceptable risks for a population from body-burdens of radioactive strontium are best made therefore using natural radium contamination as the criterion. This approach is being pursued with vigour.

Dose-response Relationship.—Meanwhile, "How does formation of bone tumours vary with dose?" Is there a relationship between natural radioactivity of bone and natural incidence of bone sarcoma? Though this has been carefully looked for, the only conclusion is that the evidence is too scanty.

Is there "growing evidence that the relation between the amount of exposure to radiations and the probability of developing long-term effects is of a linear nature"? In so far that formerly there was none at all, while recently a linear relationship has been suggested between dose to a point in the spinal marrow and the incidence of leukemia in irradiated spondylitics (Appendix B[4]), this statement is true. But radiation-induced leukemia is an odd thing. It has a much shorter latency than other radiation-induced malignant states. Some would even yet argue that it is not a malignant condition. In the experimentally induced lymphoma of the mouse the relation between total dose and fractionation of the dose is most complex and certainly not simply linear.[7]

It would be unwise therefore to use leukaemia as a model for all radiation-induced malignancies and as a justification of the thesis of somantic mutation as the cause of cancer. It is wrong moreover, to attribute to the M. R. C. report[4] opinions which it did not express. The statement, "Each unit quantity of radiostrontium absorbed by bone confers a certain probability of bone tumour formation," was not in the report but one of its signed appendices. Furthermore, the statement would suggest a linear relationship only if each unit quantity conferred the *same* probability.

In point of fact, the quantitative evidence of the carcinogenic properties of radiostrontium, and there is not much of it, suggests that the relationship is not linear and that there is some form of threshold, or effective latent period.[8,9] Therefore your conclusion, "The consequence of a linear relationship is that every H-bomb test by causing an increase of the content of strontium-90 in bone will increase the frequency of bone lesions," is as yet without foundation. The correct conclusion in the present state of scientific knowledge is that a linear relationship sets the limit and indicates the worst possible conditions, so that it would be prudent to go easy until the real facts are ascertained.

Strontium in Animal Metabolism.—*Pari passu*, it is right and proper that investigations be made on the uptake of both natural radium and the now universal strontium-90. Your leading article notes that we derive most of our calcium and strontium from milk and certain of its products. A safety factor of about 7—the cow—is built into this route by which we ingest strontium-90. Your leading article quotes a second safety factor of about 8 in going from food to the deposition of strontium in human bone. The combination of 7×8 would indeed be impressive, but is unfortunately an overstatement. Sowden and Stitch[6] find the strontium content of human bones to be, in round figures, 100 p. p. m. of ash, of which about 40% will be calcium. The strontium: calcium ratio is thus about 1:4,000. In a general diet one can derive from the data of Harrison *et al.*[10] that strontium: calcium is about 1:500. Here is the factor 8, but this includes the factor for the cow insofar as milk and its products are part of the diet of the average adult. Moreover, Harrison *et al.* calculate that the discrimination against strontium in favour of calcium by the human gut gives a factor of about 2. Unpublished observations from the same source suggest that the human bone absorbs calcium and strontium from the blood without discrimination. The best figure at the moment for the human safety factor is thus only 2. It is likely to be rather higher for alkaline earths of vegetable origin than for those derived from milk, since lactose and some amino-acids cause reduction in the factor of discrimination.[11]

Strontium in Soil and Plant.—Your leading article infers that all the strontium-90 in plants is derived from the soil. But the leaf of the plant is a very good surface for the adhesion of small particles of "fall-out" and for the absorption of strontium as well as other mineral ions.[12, 13] Thus the present contamination may be much more related to the rate of fall-out than to integrated total "fall-out."—I am, etc.

Didcot, Berks J. F. LOUTIT.

SIR.—Your leading article (*Journal*, March 30, p. 752) states that strontium-90 does not present genetic hazards since it emits only β-rays which do not penetrate to the gonads. In view of the great importance of this subject at the present time, it would be interesting to know whether this statement is based on experimental evidence or merely on supposition. If the latter, then it is difficult to accept the argument without further investigation. It may be that the writer assumed that all the available strontium-90 is deposited in the bone and therefore is unlikely to affect the gonads. However, even on this assumption the β-particles can traverse distances of up to about a centimetre in soft tissues:[1] when the testes are in the inguinal canal, they must be less than one centimetre distant from bone at some stage in their journey. This may also apply to the ovaries during development.

A second possibility which may not be excluded is the effect of any strontium-90 prior to its deposition in the bone or after subsequent mobilization. If there is any similarity between the effect of strontium and lead it may be that strontium does in fact have an effect on the soft tissues in general. Lead is well known to have a special affinity for bone, but its main impact is on soft tissues, such as the nervous system and the gut. Until, therefore, these possibilities have been excluded by experiments of suitable length in mammals, such a statement as that in your leading article may convey a false sense of security.—I am, etc.

ATOMIC ENERGY RESEARCH ESTABLISHMENT

THE RADIOLOGICAL DOSE TO PERSONS IN THE U. K. DUE TO DEBRIS FROM NUCLEAR TEST EXPLOSIONS PRIOR TO JANUARY 1956

By N. G. Stewart, R. N. Crooks, and Miss E. M. R. Fisher

1. INTRODUCTION

The size distribution of the radioactive dust particles in the cloud from a nuclear explosion depends both on the power of the weapon and on the manner in which it is exploded, whether on the ground, on a tower or high in the air. The larger particles fall to earth relatively close to the site of the explosion, but in every type of burst a considerable fraction of the total radioactivity generated is contained in fine dust particles whose rate of fall under gravity is small and which may therefore remain airborne long enough to diffuse widely throughout the atmosphere and affect large areas of the earth's surface.

The United Kingdom, being remote from all test sites used up to the present time, has been free from local effects and has provided a useful observation area in which to study the global contamination problem. In this paper, an account is given of the methods that have been used to measure the amount of radioactive material in the air above U. K., and the amount deposited on the ground, as a result of all weapons exploded between January 1951 and January 1956. Based on these measurements, an estimate is made of the integral gamma ray dose received by the average inhabitant of this country during his lifetime from all nuclear tests held to date. An estimate is also made of the dose that will ultimately be received per individual per generation if bombs continue to be exploded at the present rate.

2. PROPERTIES OF THE DUST PARTICLES

2.1 The particles reaching U. K. from the smaller type of nuclear explosion are spherical in shape, having been formed by the condensation of material which has been vaporised in the explosion. They consist mainly of fused silica or metal oxides, depending on whether the weapon has been exploded near or remote from the surface of the earth, but both types are impregnated with radioactive elements more or less uniformly throughout their volume. The particles from the thermonuclear tests over the Pacific atolls consist mainly of calcium carbonate or calcium oxide but they are shapeless, possibly due to the refractory nature of the coral on which the tests have taken place. The vast majority of the particles encountered in U. K. from all types of explosion have diameters of less than 10μ ($1\mu=10^{-4}$ cm.).

2.2 The radioactive content of explosion dust falls into three categories:

(i) Fission Product Activity (β, γ)
(ii) Neutron Capture Activity (β, γ)
(iii) Alpha Activity

Fission Product Activity

The fission products contained in the fine dust are fairly representative of those generated in the parent explosion although, under certain circumstances, some may be preferentially deposited along with the larger particles near the test site. Different types of weapon produce the same assemblage of fission products in slightly different proportions, but the rate of decay of the gross activity is almost independent of these differences and varies approximately as the inverse 1.2 power of time. Thus the activity decreases by a factor of 10 for a 7-fold increase of time as measured from the instant of the explosion. Table I shows the percentage contributions made by some of the more important fission products to the beta-ray activity from the slow neutron fission of U^{235}. Only those contributing more than 5% to the total activity at any time are included in the list. At the foot of the table are given Hunter and Ballou's computed figures[1] for the beta activity associated with the fission of 10^6 atoms of U^{235}. It is often convenient to express the fission product activity of dust in terms of the number of fissions from which this activity is derived. Thus a sample which is disintegrating at the rate of 620 disintegrations per minute (dpm) twenty days after the time of the parent explosion may be said to contain 10^6 fissions (see Table I).

Activity from Neutron Capture

Although several different radioactive elements may be created by the capture of neutrons in materials close to the reacting core of a weapon, the only significant reactions to produce gamma-ray emitters are those associated with the natural uranium which may be used as the tamper material of the bomb. This uranium is subjected to intense neutron bombardment during the nuclear explosion and the following reaction takes place:

$$92^{U238} + 0^{n1} \longrightarrow 92^{U239} \xrightarrow[23.5m]{\beta-} 93^{Np239} \xrightarrow[2.33d]{\beta-} 94^{Pu239} \xrightarrow[long]{\alpha} \ldots \quad (1)$$

Chemical analysis of the debris shows that in general about one neutron is captured in this way for every fission that occurs, both in nominal bombs and in thermonuclear explosions. The U^{239} decays completely before reaching the U.K. but at four days after time of burst the Np^{239} disintegration rate reaches a peak relative to that of the fission products and accounts for about 60% of the observed activity at that time.

In addition to this, a smaller number of the neutrons in a thermonuclear explosion undergo an (n,2n) reaction with U^{238} to form 6.7 day U^{237} which is also a (β, γ) emitter.

Despite the fact that Np^{239} and U^{237} contribute much to the gross activity of the dust particles in the first few days after burst, their short half-lives and the softness of their gamma rays prevent them from adding significantly to the hazards associated with the fission products.

Alpha-Particle Activity

By far the most important alpha-particle emitter in the explosion dust is Pu^{239}. Consider first a nominal bomb of efficiency 20% with plutonium as the

[1] Hunter, H. F. and Ballou, N. E. ADC-65.

fissile material. Since one plutonium atom is used per fission, there will be a residue of four atoms/fission after the explosion. But since (equation 1) we may assume that one atom of plutonium is created per fission by neutron capture in U^{238}, the dust particles from this type of explosion will contain five plutonium atoms per fission. If U^{235} is used as the fissible material, the content will be one plutonium atom per fission; this same figure has been found to hold for thermonuclear weapons.

2.3 Between 20% and 30% of the activity contained on the spherical particles collected from the smaller nuclear explosions has been found to be soluble in water. The mean figure for the particles from thermonuclear tests over the Pacific atolls is 55%.

3. MEASUREMENTS OF DUST CONTENT OF AIR

The atmosphere has been sampled in a routine manner for radioactive dust since 1948 by attaching air filters to the aircraft which carry out the standard meteorological flights from Aldergrove, Northern Ireland. The frequency of sampling has varied throughout the period from daily to three times per week. The aircraft fly for about eight hours on a triangular course over the Atlantic; the main flying on each sortie is done at 1700 feet and at 18,000 feet with occasional descents to sea level and thus a reasonable sample of the dust content of the lower atmosphere is obtained. Each plane carries a cylindrical filter of length six inches and diameter 3½ inches consisting of a mat of esparto grass paper inside a wire cage. The collection efficiency of this arrangement is about 100% for particles greater than 3μ but this drops to 70% for the finest sizes created by nuclear explosions.

The average amount of air sampled during each flight has been measured by comparing the activity on a cylindrical filter with the activity collected on a disc filter of the same material flown at the same time, the disc being mounted in a long tube containing an orifice plate so that the air flow could be determined during flight. In this way it has been estimated that each routine filter sample contains the active dust from 1530 kg. of air.

The air has also been sampled since early 1952 over successive 24 hour periods at ground level near Harwell by fitting standard cylindrical filters to a powerful blower which provides a daily throughput of 7400 kg. of air.

The beta activity of the filters is measured by mounting them coaxially over a calibrated cylindrical geiger counter type B12E. The wall of this counter is thick enough to eliminate effectively the soft beta radiations of Np^{239} and U^{237} and the system thus provides a measure of the fission product activity alone. The measured disintegration rate of a sample of known age can be expressed in terms of fission units by using the computed curves of Hunter and Ballou. The Np^{239} and U^{237} activities are determined separately by chemical analysis.

4. RESULTS

4.1 *General.*—When a nominal bomb is exploded in, say, Nevada, the dust cloud rises to a height of perhaps 10,000–12,000 metres and travels east with the prevailing westerly winds. As the cloud travels it diffuses both laterally and vertically and ultimately contaminates the lower atmosphere across a broad front at great distances. Although on the average the cloud from a Nevada explosion crosses U. K. on the fifth day after time of burst and thereafter every four to seven weeks as it circulates round the world, the behaviour of any one cloud can depart considerably from this average and to obtain a general idea of the way in which the concentration of dust varies with distance downwind or with time, it is convenient to consider the concentrations over U. K. of the fission products from a series of explosions whose times of burst are close enough together to allow them to be considered as a single event, at least throughout a period starting some three to four weeks after the mean time of burst.

The specific activity of air above U. K. in the period following the Russian and American tests in the autumn of 1951 has been plotted in Fig. 1A. In this diagram, time is measured from the mean date of the individual explosions, and the specific activity of the air, as determined from the Aldergrove flights, has been averaged over periods of approximately fourteen days to give a figure representative of a significant fraction of the circulation path of the air, and to smooth out short-period variations. In this presentation, earlier points are

omitted since the method cannot reasonably be used within the actual period when the explosions are occurring. A smooth curve has been drawn through the experimental points and it has been found by experience that the shape of this curve is quite characteristic of explosions of near nominal size which take place in the middle latitudes of the northern hemisphere. The curve has been corrected for the radioactive decay of the fission products according to a composite decay curve computed from the sum of the individual decay curves, giving the dotted line in Fig. 1 which can then be taken to represent the decrease with time of the specific air content of the dust itself or of the longer-lived isotopes.

The decrease with time of the specific dust content of the air over the U. K. can be due to increased spread of the cloud or to deposition or both. Vertical spread above 12,000 metres is prevented by the very low diffusion rates in the stratosphere (see below). There is also a barrier of stable air in the lower atmosphere (troposphere) reaching as far as 25°N of the equator which prevents widespread diffusion to the south. Finally, direct observations of the lateral spread of Nevada clouds by sampling planes based in Gibraltar and in Scotland suggest that lateral diffusion is virtually complete by the time the clouds have made one circuit of the world. All the points in Fig. 1 refer to clouds which satisfy this criterion and we must conclude that the dotted line in Fig. 1A represents the rate of removal of atmospheric dust from the atmosphere by deposition alone and that half the material is removed in approximately 22 days.

The behaviour of the clouds from thermonuclear explosions is quite different. The fortnightly averages of the specific air activity obtained from the Aldergrove flights following the Pacific tests in the spring of 1954 have been plotted in Fig. 1B. There is no sharp decrease of airborne activity such as was obtained after the Nevada explosions, and when the correction is put in for radioactive decay it will be seen that the concentration of dust has in fact been increasing throughout the ten months following the mean date of the explosions. The explanation is that a thermonuclear dust cloud penetrates into the stratosphere and reaches a height of the order of 30,000 metres soon after the explosion. Diffusion is a very slow process in the stratosphere and material returns to the lowest layers of the atmosphere at a much slower rate than in the case of the nominal bomb cloud. The gap in the record in Fig. 2 occurs during the period when the lower atmosphere was further contaminated by the explosion of several Russian nominal-sized bombs in the late Autumn of 1954. This contamination decreased in the manner shown in Fig. 1A for this type of bomb, enabling measurements to be resumed on the residual thermonuclear contamination in January and February, 1955.

Direct confirmation of the hypothesis that the thermonuclear explosion dust is held back in the stratosphere has been provided by a series of experiments conducted in the Autumn of 1954 and repeated in the Spring and Autumn of 1955. In these experiments the concentration of activity was measured at various heights in the atmosphere up to 15,000 metres. The mean concentrations, averaged over a period of two months in the Autumn of 1954, are shown in Fig. 2 which demonstrates quite strikingly the existence of a large accumulation of fine dust in the stratosphere several months after the tests. The origin of the dust was identified by chemical analysis of the fission products.

4.2 *Mean Concentration of Beta and Gamma Activity in Ground Level Air.*— The dust clouds from Nevada and Russia pass over U. K. on their first circuit of the world before they have diffused to ground level, so that the activity does not reach high values in the surface air over this country. The peak concentrations, averaged over 24 hours, are generally in the region of 5 dpm of beta activity per cubic metre of air, but individual peaks of 25, 15, 10 and 8 dpm/m^3 have been observed. Thermonuclear explosions produce smaller concentrations because of the slow rate of diffusion from the stratosphere, the highest observed figure being 0.5 dpm/m^3. The average concentration of activity from all bombs exploded within the period April 1952, to January 1956 was 0.5 dpm/m^3, and most of this came from explosions in Nevada. The mean concentration in the eight months following the 1954 Pacific thermonuclear tests was only 0.1 dpm/m^3. Although much of the material from the thermonuclear explosions has yet to reach ground level, the average over the next few years due to bombs already exploded is not expected to exceed this figure of 0.1 dpm/m^3.

The external gamma dose rate corresponding to 0.5 dpm/m^3 of fission product activity in air has been computed by applying Chamberlain's method[2] to the gamma energy spectrum of the fission products. Including the dose rate due to Np^{239} and U^{237} the total figure is 10^{-3} milliroentgen (mr) per year to a person fully exposed to the radiation.

It is useful to compare the figures just given with those for the natural radioactive content of air. The combined disintegration rate of the natural RaB and RaC in the atmosphere at Harwell, averaged over the period November 1950 to March, 1951 was 128 dpm/m^3. The corresponding gamma dose rate is about 0.4 mr per year. The Harwell values for the RaB and RaC disintegration rates in air are, on the whole, smaller than those found elsewhere; mean values of 220 dpm/m^3 and 470 dpm/m^3 have been found at Windscale[3] and Cambridge[4] respectively while much higher figures are implied by recent Radon measurements in London.[5] Moreover, under stable atmospheric conditions, the RaB and C content of the air near ground level may reach values greatly exceeding the mean levels. The highest individual peak in the Harwell observations was 1800 dpm/m^3 which is 14 times the average value; similar values have been observed by other workers.

4.3 *Mean Concentration of Sr^{90} and Pu^{239} in Ground Level Air.*—No routine measurements have been made of the concentration in air of any individual isotope but it is possible to estimate the figures for those with relatively long half-lives. This will be done for the important isotopes Sr^{90} and Pu^{239}.

The mean fission product content of the air in the period April 1952 to January 1956, derived by calculation from the observed beta activity, was 5×10^5 fissions per cubic metre. Using an apparent fission yield of 4%, which is not inconsistent with radiochemical evidence, it follows that the mean concentration of Sr^{90} in the air within this period was 4×10^{-16} μc/c.c. The I. C. R. P. occupational m. p. l. is 2×10^{-10} μc/c.c.[6]

An upper limit for the mean plutonium concentration has been calculated in a similar manner, by allowing five atoms of Pu^{239} per fission from an atomic weapon in the nominal size range and one atom per fission from thermonuclear weapons. The mean concentration over the same period is thus found to be 3×10^{-17} μc/c.c.; the I. C. R. P. occupational m. p. l. is 2×10^{-12} μc/c.c.

5. DEPOSITION OF RADIOACTIVE DUST: SAMPLING METHODS

Dust particles which are too small to have a significant falling speed in air are removed from the atmosphere in two ways:—

(i) by washout in rainwater

(ii) by dry deposition directly onto surfaces.

Continuous measurements have been made since early in 1951 of the fission product content of rainwater falling on roofs at Milford Haven, Pembrokeshire, and Chilton, Berkshire. The roofs have been coated with chlorinated rubber paint which is chemically inactive and provides a smooth surface over which the rainwater and the entrained dust flow readily. The water is passed through cylindrical esparto grass filters of heavier gauge than is used for air filtration. The filters are exposed for 24 hour periods during rain and, after removal, are dried and their activity measured on the standard counting assembly; a suitable interval of time is allowed for the short-lived natural Radon and Thoron daughter products to decay before counting is started. Allowance is made for the solubility of the material when deriving the true deposition figures from the measured counting rates; check measurements of the solubility are made at intervals during a particular series of explosions.

The problem of the direct deposition onto surfaces is a complex one and some aspects of it are now being studied by Chamberlain at Harwell.[7] Owing to the complexity of the earth's surface it is obvious that realistic measurements of the amount of radioactive dust from nuclear explosions deposited in this way would be impossible. But since Chamberlain's early work has shown that, under certain conditions, this mechanism of deposition can be as important as rainwater deposition, it cannot be lightly ignored. It is thought, however that in the cir-

[7] Chamberlain, A. C. A. E. R. E. Report HP/R 1261.

cumstances peculiar to deposition from the fine dust clouds from atomic and thermonuclear explosions, deposition by rain is by far the more important factor. The reasons for this view are given in the following section.

It will be shown in para. 831 that on the average 80% of the integrated gamma dose recived by an individual in U. K. from radioactive material deposited by *rain* after a Nevada explosion is due to the deposition that takes place while the cloud is crossing U. K. for the first time. It has already been stated that the concentration in the air at ground level during this first passage is generally low, and, in fact, the transfer rate from from air to ground would have to be impossibly high before it could add significantly to the rain deposition. To investigate what happens on subsequent circuits of the cloud, when vertical diffusion is complete, an experiment was carried out in which the deposition by rain in four successive fortnightly periods was compared with the dry deposition onto a glass plate covered by a film of vaseline. The results obtained in the four periods were very consistent and showed that the deposition by normal rainfall was four times that due to dry deposition on the sticky surface. It was therefore concluded that since the rain deposition from the cloud during its second and subsequent circuits of the world was less than that during the first, the rainwater measurements alone should provide a fair measure of total deposition. In any case, the method of sampling adopted ensures that any radioactive dust deposited on the collecting roofs during dry spells is washed off by subsequent showers and included in the rainwater activity measurements.

The weighting factor in favour of rain deposition is even greater in the case of dust from thermonuclear explosions. Since the dust is fed slowly into the troposphere from the stratosphere and is subsequently removed by deposition, a gradient of activity is maintained in the lower atmosphere and the concentration near ground level is very small (Fig. 3). The rain brings down activity from regions where the concentrations are comparatively high and it is estimated that for these reasons, rainwater deposition exceeds dry deposition by a factor of about twenty.

6. DAILY DEPOSITION LEVELS AT CHILTON AND MILFORD HAVEN

The daily deposition records at Chilton and Milford Haven are similar in general although occasionally differing markedly in detail. All daily deposits of surface activity greater than 2 mc/km^2 observed between February 1951 and January 1956 have been arranged in groups and the frequencies of occurrence of the various groups are given in the following table:

Range of Values of Deposited Activity (mc/km^2)	Frequency of Occurrence	
	Chilton	Milford Haven
2-10	83	76
10-20	9	5
20-40	3	1
40-60	3	----------
60-80	1	----------
80-100	----------	1

The highest daily deposit at the sites was 73 mc/km^2 at Chilton and 93 mc/km^2 at Milford Haven; these occurred in heavy rain about the same time, some five days after the explosion of a weapon in Nevada in the Autumn of 1951. The highest deposition in a single day from a thermonuclear weapon test was 10 mc/km^2 at Chilton and 39 mc/km^2 at Milford Haven.

7. DEPOSITION FROM THE 1952 NEVADA TESTS

7.1 Before proceeding to the final stage of calculating the gamma dose from the fission products deposited to date, it is important to consider in some detail the deposition measurements from one particular series of explosions in order to check that the results are in fair agreement with expectation. It is particularly suitable to choose for this purpose the Nevada tests in the period April–June 1952 since the U. S. A. E. C. have published a paper [8] summarising

[8] Eisenbud, M., and Harley, J. H. Science 117, 141 (1953).

their own deposition measurements within the U. S. during this series and a useful comparison of results can be made.

7.2 *U. K. Measurements in 1952.*—The 1952 Nevada tests consisted of eight explosions between April 1st and June 5th, the mean date of burst being May 6th. During this period and up to the time in late November when the atmosphere was further contaminated by radioactive dust from a Pacific test, the usual daily measurements were made at Chilton and Milford Haven of the activity deposited in rainwater. The quantity to be computed, to simplify comparison with the U. S. results, is the cumulative value of the deposited activity on December 6th, i. e. seven months after the mean date of burst, when deposition was virtually complete. The approximate method used was to add up the total deposition for each individual month and to calculate the probable value of this on December 6th using the Hunter-Ballou decay curve for the fission products from U^{235}. The only refinement to this method was that each heavy deposition resulting from the passing over U. K. of a single identifiable cloud on its first transit of the earth was followed through individually on its own decay curve.

The calculations show that the activity deposited at Chilton and Milford Haven amounted to 6350 dpm/m² and 8200 dpm/m² respectively on 6th December, 1952. The lower figure at Chilton is due to the fact that during an important part of the deposition period the rainfall was much lower there than that at Milford Haven, where it was very close to the average for U. K. The higher figure may therefore be taken as representative for this country.

7.3 *Comparison of British and American Results in 1952.*—In the U. S. the dust is collected on horizontal sticky plates which have the property of retaining the dust brought down by rain in addition to that deposited directly from the air. A paper has been published[8] giving an analysis of the measurements made at a network of 121 stations within U. S. during the period following the 1952 Nevada etsts. The average values of the deposited fission product activity are given at several distances between 300 and 2,400 miles downwind from the test site. The quoted figures refer to the cumulative values of the deposited activity on 1st January 1953, but using the conversion figures given in the report, these have been adjusted to a reference date of 6th December 1952 and are plotted in Fig. 8. One additional point not included among the original figures has been derived for the distance of 17,000 miles by averaging the deposition figures obtained at several places on the U. S. West coast and shown in the map in Fig. 1 of the report. This additional figure will include not only the deposition of material which has travelled once around the world but also that due to any temporary "back-flow" from the test site, and it represents therefore an upper limit for deposition at 17,000 miles downwind.

The U. K. figures have been plotted for comparison in Fig. 8, and the agreement is seen to be fairly good. No rainfall figures are given in the U. S. report for the period in question, but the difference in the mean rainfalls of U. S. and U. K. is not large enough to invalidate the comparison.

7.4 *Check on the Order of Magnitude of the U. K. Figures.*—The deposition of active material from bomb explosions in Nevada is likely to be confined to the Northern Hemisphere since the diffusion of matter across the stable air barrier is slow and is not likely to reach significant proportions in the time required for the bulk of the material to be deposited. It is therefore possible to estimate the average ground surface activity on the assumption of uniform distribution.

The number of fissions in a nominal bomb explosion is approximately 2.4×10^{24}.[9] The Hunter-Ballou decay curve shows a disintegration rate of 3.5×10^{-7} dpm per fission at +7 months. The area of the Northern Hemisphere is 2.5×10^{14} m²

$$\text{Calculated specific ground activity}=\frac{3.5\times10^{-7}\times2.4\times10^{24}}{2.5\times10^{14}}$$

$$\therefore \text{ per nominal bomb at } +7 \text{ months} = 3350\, dpm/m^2$$

The observed representative figure was 8200 dpm/m² from eight bombs exploded. Two of the bombs were described in the Press as very small and it may

[9] The Effects of Atomic Weapons, U. S. Government Printing Office, Washington 25, D. C. (1950).

be assumed as an approximation that the fission product release during the series was equal to that from six nominal bomb explosions.

$$\therefore \begin{array}{l}\text{Observed specific ground activity} = 8200/6 \\ \text{per nominal bomb at } +7 \text{ months} = 1367 dpm/m^2\end{array}$$

The observed figure is therefore of the expected order of magnitude, and the U. K. deposition measurements thus show satisfactory agreement with both the U. S. result and with the calculated values.

8. COMPUTATION OF THE GAMMA RAY DOSE FROM DEPOSITED FISSION PRODUCTS

8.1 *General Procedure.*—The gamma ray dose received over a period of 50 years due to all bombs exploded before January 1956, will first be calculated for the case of a man standing on an infinite plane surface. This will be done by calculating the total dose to the man from each single deposition and summing the series. The figure thus obtained will be larger than the dose received in practice since the shielding provided by buildings against gamma rays and the removal of activity from the earth's surface by drainage and by weathering have been ignored. Suitable adjustments to take account of these factors will be considered later in the report.

8.2 *Method of Calculation.*—Consider first the dose rate at a point above a plane uniformly contaminated with fission products of some particular age. The fission products emit a large number of gamma rays whose energies and rates of emission can be obtained from the literature. The dose rate at the point can therefore be regarded as the sum of the dose rates from a number of uniform deposits each of which emits gamma rays of one energy only. But even this simplified problem has not been solved numerically for the general case owing to the complex nature of gamma ray scattering and absorption. However, Chamberlain [2] has devised an approximate method for estimating the dose rates at various heights above a plane for all gamma energies, and this has been shown in recent measurements at A. E. R. E.[10] to give an accurate result for the particular case of Co^{60} gamma rays. There is no guarantee that the method is equally accurate at all other energies, but the error cannot be large enough to vitiate the present calculations.

Dale, Kendall and McKendrick [11] have applied Chamberlain's method to the gamma rays emitted by the fission products of U^{235} and Pu^{239} and have computed the dose rates received by a man standing on an infinite plane uniformly contaminated with those products at times between one hour and three years. The two sets of dose rates do not differ by much and those for U^{235} have been used in the computations which follow; additional values have been worked out for times between 3 and 50 years. Some of the more important quantities derived from Dale's data in the intermediate stages of computations have been listed in Table II as they illustrate several features of the fission product gamma activity. Column 2 shows how the dose rate from a specified surface activity varies with the age of the fission products; thus the dose rate from a deposit of fission products one day old is four times as great as that from an equally active deposit of products three years old. Column 3 shows how the dose rate from a particular deposit varies with time; the decrease is due mainly to the radioactive decay of the fission products. Column 4 gives the total dose received within a period of 50 years from depositions which occur at various times after an explosion; these figures allow the integrated dose from any deposition of known age to be rapidly assessed. The increase of the figures with time is due to the fact that old fission products decay less rapidly than young and therefore, for a given initial surface activity, deliver a greater integrated dose. The last column shows the integrated dose between various times T and 50 years from a deposit whose specific activity at one day after time of burst is 1 c/km². This information has been plotted in Fig. 4 which demonstrates the rate at which the dose from a particular deposit is delivered. Since no deposition has yet taken place in U. K. until after the fourth day from the time of an explosion, the earlier points are of academic interest only. The graph shows that 50% of the total dose from a deposition occurring on the fourth day after an explosion is received within the following 26 days.

8.3 *Results of the Dose Calculations—*

8.3.1 *Atomic Bombs of approximately Nominal Size.*—Since the deposition from these bombs is completed within a few months, the calculation of the integrated dose by the procedure outlined above is a simple matter. The calculations have been done in two stages. The integrated doses from the individual identifiable depositions from clouds crossing U. K. for the first time have been calculated by combining the surface activity of these deposits with the data given in column 4 of Table II. The dose from activity deposited subsequently is determined in a similar manner, but here the depositions have been summed over fortnightly periods and the effective age of the mixed products measured from the mean time of burst of the weapons. The results of the calculations are given in some detail below for the eight Nevada explosions in 1952.

	No. of Bomb	Integrated Dose within 50 years (μr)	
		Chilton	Milford Haven
Deposition from clouds on first circuit of world	1	12	17
	2	0	0
	3	76	20
	4	8	8
	5	114	6
	6	14	166
	7	13	39
	8	59	71
Total, first time round		296	327
Residual, from subsequent deposition		56	91
Total integrated dose		352	418

The resultant integrated doses at the two sites do not differ by much, but it will be observed that the main contributions at each place come from different bombs. About 80% of the total dose is produced by deposition from clouds crossing U. K. for the first time.

The results obtained from seven test series of similar type involving the explosion of some 60 weapons are summarised in the top part of Table III. The average integrated dose from the deposited activity is 66 μr per explosion, and on this basis an allowance has been made for another 15 explosions from which dust was probably deposited in U. K. but for which no measurements were made. The figures for the number of weapon exploded have been obtained from press reports. The British tests in Australia have been neglected as the clouds from these were not detected in the North Hemisphere. The integrated dose from all bombs in the nominal size range exploded up to January 1956, based on the mean of the measurements at Chilton and Milford Haven, is 4.9 mr.

8.3.2 *Thermonuclear Explosions.*—The computation of the integrated dose in U. K. due to dust from thermonuclear tests falls naturally into two parts. Firstly, there is that part of the dose arising from material which is already on the ground and secondly, that due to material which has yet to be deposited and is at present airborne.

The first part of the calculation is a repetition of that already carried out for the nominal weapons, but there are some differences worthy of note. The integrated dose is no longer dominated by the deposition which takes place in the first few days after burst. The rate of deposition of activity is a slowly decreasing function of time of the type shown in Fig. 1B, and the mean daily deposition one year after burst adds more to the integrated dose than that at any earlier time. Again, since the time scale of the deposition is long, the records are frequently interrupted when the lower atmosphere is temporarily contaminated by dust from nominal bomb tests and a certain amount of interpolation is necessary; this presents no serious difficulty since the deposition rates are slowly varying. The results of the computations for the thermonuclear test series in the Pacific in 1952 and 1954 are given in the lower part of Table III; the figures have been separated into those based on direct measurements of deposited activity and those based on interpolation.

In order to forecast the integrated dose from active dust still to be deposited, estimates are required of the total amount of activity in the atmosphere and of its rate of descent.

An estimate of the fission product content of the atmosphere above U. K. in September 1954 can be obtained by extrapolating the graph of Fig. 2 and integrating under the curve to obtain the total fission product content of an infinite vertical column of cross-section 1 square metre. This extrapolation has been done by producing the curve of Fig. 2 linearly to a height of 10mb—the estimated initial height of the cloud—and assuming the concentration above that level to be constant. The value of the integral thus determined is 3×10^{12} fissions/m^2. The deposition rates at Chilton and Milford Haven during the same period were equivalent to 4.7×10^{11} and 2.6×10^{11} fissions/m^2/year respectively, or 16% and 9% of the content of the column per year. The same integration carried out with data obtained in January and February 1955 showed that the content of the column had increased since September to a value of 10^{13} fissions; the deposition rate had risen in proportion and was 12% per year at both sites. Whether the increased concentration is a seasonal effect or represents a gradual downwind or lateral diffusion into the atmosphere above U. K. from regions of higher concentration cannot be answered confidently. It is hoped that further observations will help to clarify this point. The present view is that the increase may be due to the slow gravitational settling of the fine dust in the rarified air of the stratosphere and that the higher levels of the stratosphere may now be depleted of activity. On this hypothesis, the value of the integral obtained in January and February 1955 may well be an overestimate of the content of the column, but it will be accepted here as the basis of the remaining dose calculations. A rough check can be made on the magnitude of the figure. It is reasonable to suppose that by the beginning of 1955 the lateral spreading of the clouds from the 1954 Pacific explosions was complete (activity reached U. K. within 12 days of the explosion on March 1st) and that the air activity above U. K. was therefore a fair sample of the world distribution. The total fission content of the atmosphere can then be calculated by summing the content of the column above U. K. (10^{13} fissions/m^2) over the area of the surface of the earth (5×10^{14} m^2); the result is 5×10^{27} fissions in the atmosphere in February 1955. This number of fissions is associated with the release of 30 megatons of energy (in the conventional units, a megaton of energy is the energy derived from the explosion of a million tons of TNT). Nothing is known of the total energy released in the 1954 Pacific tests but a typical thermonuclear weapon is commonly suposed to have a power of about 10 MT. The computed figure of 30 MT, and by implication the air activity figure from which it was derived, is therefore of the right order of magnitude and in the absence of definite weapon information, no more than this can be claimed.

The second part of the dose calculation, then, is based on an atmospheric content of 10^{13} fissions per unit column in early 1955 from the 1954 Pacific tests. A small factor of safety is introduced by assuming that deposition takes place at the rate of 20%. The computed integrated dose from the activity yet to fall is then 20.3 mr. Observations of deposition from the 1952 tests were too frequently interrupted for a similar calculation procedure to be adopted. It has been found experimentally, however, that at comparable times after burst the air concentrations and deposition rates from the 1952 and 1954 test series are in the ratio of 1:3.6. The residual integrated dose given in Table III for the 1952 tests is based entirely on the calculations for the 1954 series, using this ratio.

The figures for the Russian thermonuclear explosion in 1955 are based on the Russian statement of the power of the airburst bomb as being in the megaton range.

8.3.3 *Estimate of a Realistic Integrated Dose for U. K.*—The estimated total dose received by a hypothetical inhabitant of the U. K. standing on an infinite plane is about 35 mr in the course of 50 years from all explosions up to December 1955 (Table III); thermonuclear explosions account for about 30 mr of this total. In practice, only a small fraction of this estimated dose will be received by the average inhabitant of this country. Much of the activity brought down by rain will be washed into drains, particularly in built-up areas, or washed down crevices in the open country. This is particularly true of the activity from thermonuclear explosions, 55% of which is soluble. A factor of three to take account of this aspect would appear to be conservative. Much protection is provided by ordinary buildings against the gamma rays from the fission products which do remain in the surface of the ground. Measurements have recently been carried out at A. E. R. E. of the protection provided by a conventional semi-detached house against a uniform deposit of Co^{60} on the ground.[13] The average

[13] Stewart, N. G., Crooks, R. N., Chisholm, J. M., Gale, H. J., A. E. R. E. Report HP/R. 1782.

protection factor was 20. It can be shown by calculation that the gamma rays from Co^{60} are suitable substitutes for fission product gamma rays in this type of experiment. The protection afforded by multi-storey buildings could be greater than this but, to remain conservative, we choose a representative protection factor of seven based on the occupant of a semi-detached house who spends an average of 2½ hours per day out-of-doors. This brings the overall protection factor to 21. A more realistic estimate, therefore, of the total dose to be received within the period 1945-1995 by the average inhabitant of this country due to deposition from all bombs exploded up to January 1956 is 1.7 mr.

It is useful to calculate the probable dose per generation on the assumption that nuclear weapons continue to be exploded at the present rate for a very long time. Under these conditions, the dose within any 30-year period will build up to a flat maximum several generations hence. For the purpose of this calculation we assume, arbitrarily, that all the fission products released up to 31st December, 1955 were released within a period of three years. It can be shown rigorously that if the dose to *infinity* from a single year's explosions is X mr, then the 30-year generation dose in the equilibrium state will be 30 X mr. The calculations summarised in Table III have been extended to include the period between 50 years and infinity, and the total dose to infinity from all bombs fired to date is then found to be 56.5 mr for a person in the open. On the argument just described, it follows that the ultimate generation dose will be 565 mr under the same conditions. For the average individual (protection factor of 21) the estimated generation dose will be 27 mr.

9. DEPOSITION OF SR^{90} AND PU^{239}

9.1 *Levels of Sr^{90} and Pu^{239} on U. K. Soil.*—Since May 1st 1954, rainwater samples have been obtained at Milford Haven by collecting the rain falling within successive three-weekly periods in a polythene funnel of area 0.22 m². These samples have been analysed radiochemically for Sr^{90} by R. G. D. Osmond at the A. E. R. E. Woolwich oustation, and the cumulative curve of deposition of Sr^{90} is shown in Fig. 5 in units of milicuries of Sr^{90} per square kilometre. The level of 0.77 mc/km² in April 1954 has been deduced from previous gross fission product measurements, using an Sr^{90} yield of 4%. The mean rate of fall over the period May 1954–March 1956 is 2.3 mc/km².

Using our figure for the mean rate of deposition of stratospheric dust—12% per year—this implies that the ground content of Sr^{90} due to bombs exploded before January 1956 will pass through a maximum of 14 mc/km² in 1968. If the present rate of firing continues indefinitely, the Sr^{90} will build up to an equilibrium ground value of about 0.2 C/km².

By way of comparison, Eisenbud[13] has reported that the top foot of soil in U. S. contains an average of 0.4 C/km² of Ra^{226} and a similar figure is expected to hold for the soil in this country.

The amount of Pu^{239} deposited in the U. K., deduced from the gross fission product measurements, is found to be 0.08 mc/km² in December 1955. This is expected to rise to a value of 0.4 mc/km² from bombs exploded up to the end of 1955. If the present rate of firing continues, the plutonium content of the soil will increase steadily and will reach a value of about 0.1 mc/km² for each year of firing.

9.2 *Levels of Sr^{90} and Pu^{239} in Rainwater.*—The mean concentration of Sr^{90} in Milford Haven rainwater between December 1952 and December 1955 was 1.7 $\mu\mu$c/litre. The mean concentration in 1955 was 3 $\mu\mu$c/litre and if the present rate of firing continues indefinitely an equilibrium level of 8 $\mu\mu$c/litre will be reached in about 10 years time. The concentration of Sr^{90} in drinking water is likely to be much below that in rainwater because of filtration and adsorption in soil. The occupational m. p. l. for Sr^{90} in water is 800 $\mu\mu$c/litre.[6]

The average concentration of Pu^{239} in rainwater during the three year period ending December 1955 has been computed from the gross fission product deposition figures, the value being .03 $\mu\mu$c/litre. An equilibrium value of .08 $\mu\mu$c/litre will be reached in ten years time if firing continues at the present rate. The occupational m. p. l. for Pu^{239} in water is 3000 $\mu\mu$c/litre.

10. THE PROBLEM OF C^{14}

From the official data on the nominal bomb given in the Effects of Atomic Weapons ([9]) it is safe to assume that, of all the neutrons which are not used

[13] Hearing before Joint Committee on Atomic Energy of U. S. Congress, April 15th, 1955.
[14] Libby, W. F., Radiocarbon Dating, Univ. of Chicago Press.

up in the fission chain reaction, not more than one escapes into the air for every fission that takes place. Most of these escaping neutrons are ultimately captured in Nitrogen to form 5600 year C^{14}. As an upper limit we may therefore presume that one atom of C^{14} is formed per fission. This implies that about 300 curies of C^{14} are formed in a nominal bomb explosion. The estimated amount of 28 year Sr^{90} formed at the same time by fission is 2500 curies. But since the m.p.'s for C^{14} in air and water are greater than those for Sr^{90} by factors of 7×10^3 and 10^5 respectively (9), it would appear that the amount of C^{14} in the air presents a relatively minor hazard.

The long-term effect can best be studied by comparing the amount of C^{14} created in nuclear explosions with that which is naturally present in the world as a result of cosmic ray reactions. It follows from our previous assumptions that the present rate of firing is adding no more than .07% annually to the natural world content of C^{14}. (14) The importance of this may be gauged from the fact that the natural C^{14} in the world contributes about 1% of the normal background dose to the human body.

11. SUMMARY

The size distribution of the radioactive dust particles in the cloud from a nuclear explosion depends both on the power of the weapon and on the manner in which it is exploded, whether on the ground, on a tower or high in the air. The larger particles fall to earth relatively close to the site of the explosion, but in every type of burst a considerable fraction of the total radioactivity generated is contained in fine dust particles whose rate of fall under gravity is small and which may therefore remain airborne long enough to diffuse widely throughout the atmosphere and affect large areas of the earth's surface. These particles are removed from the atmosphere mainly by rain.

The most important radioactive components of the dust are the numerous fission product nuclei which decay at various rates and emit both beta and gamma rays of a wide range of energies. As time proceeds the shorter-lived isotopes in a representative sample of fission products decay into insignificance in comparison with those of longer half-life, and after about eight years nearly all the gamma activity stems from the single isotope Barium 137 daughter of Caesium 137 which has a half-life of 30 years. The gamma rays from fission products suspended in the air or deposited on the surface of the ground add to the general level of background radiation and increase the external radiological dose to the human body. Some of the individual isotopes may enter the human body through biological chains and produce internal effects. The most important of these is generally considered to be 28-year Strontium 90 which follows Calcium in biological systems and is deposited in bones from which it is removed very slowly.

The amount of activity deposited in rain has been measured at Chilton, (Berkshire) and Milford Haven (Pembrokeshire) since January 1951, by passing rainwater through filters whose radioactive content is then measured on a conventional Geiger counter assembly. There is no significant difference between the aggregate results obtained at the two sites. An example, given in some detail in the report, shows that the measured total deposition in the United Kingdom from the 1952 test explosions in Nevada is in good agreement with the very full data which the United States have published for the series.

The atmosphere between 500 metres and 5500 metres above the U. K. has been sampled for radioactive dust about three times weekly since 1948 by attaching air filters to the aircraft which carry out routine meteorological flights from Northern Ireland. In addition, the air at ground level near Harwell has been monitored continuously since early 1952.

The records reveal one clear and important difference between the clouds from weapons in the nominal size range (similar to that exploded at Nagasaki) and those from the large thermonuclear explosions in the Pacific. It is found that the concentration of fine dust in the atmosphere from nominal size explosions decreases in a regular and characteristic manner with time and that half the dust is removed by deposition in 22 days. The fine dust from a thermonuclear explosion, on the other hand, enters the stratosphere soon after burst and from there it diffuses downward so slowly that only 10–20% of the dust is deposited annually. Much of the activity from the 1952 and 1954 thermonuclear tests in the Pacific is therefore still in the stratosphere, and in order to determine the possible effects of these explosions in the U. K. it is necessary to form an estimate of this amount. This has been achieved by extrapolating the results obtained from systematic surveys of the radioactive content of the air between

ground level and 15,000 metres carried out in September 1954, February 1955 and September 1955.

The gamma ray dose from each individual deposit of fission products has been calculated initially for the idealised case of an individual standing on an infinite flat plane. A protection factor of three has then been introduced to take account of the material which is washed into drains or is otherwise removed from the topmost layer of the earth's surface. This factor is believed to be conservative, since about one half of the material already deposited has been found to be soluble in water. An additional factor of seven has been allowed for the shielding provided by buildings against the gamma rays from fission products. This figure has been derived from measurements carried out at A. E. R. E. with the gamma rays from Cobalt 60, and is based on the assumption that the average individual spends 2½ hours daily out-of-doors.

The individual doses have been summed, and the total external dose to be received by the average inhabitant of the U. K. due to material deposited on the ground from bombs exploded before 1st January 1956 is estimated to be 1.7 mr. About 70% of this dose is associated with material which has yet to be deposited. The dose due to debris suspended in the air near ground level is negligible by comparison. It has also been estimated that if weapons continue to be fired at the present rate for an indefinite period, the ultimate dose per individual per generation will be 27 mr; this level will be reached in approximately 100 years.

The concentration of Sr^{90} in the ground in the U. K. has been obtained from radiochemical analysis of the rainwater falling at Milford Haven. Based on the results of this analysis an estimate has been made of the possible future levels of Sr^{90} in U. K. soil should weapon testing continue at the present rate for an indefinite period.

All the important computed figures are given in the table at the end of this summary.

Summarised results

Gross Fission Product Activity in Air		
1. Mean conc. of activity in ground level air (1952–1955).	0.5 dpm/m^3	Mean activity due to the natural RaB and RaC in atmosphere (measured at Harwell) = 128 dpm/m^3.
2. Peak conc. in same period	25 dpm/m^3	Peak value = 1,800 dpm/m^3.
3. Mean Gamma dose rate to a person fully exposed to this radiation.	10–3 mr/year	
Gamma Dose from Deposited Activity		
1. Estimated dose to the average person in U. K. in a period of 50 years from all bombs exploded before 1.1.56.	1.7 mr	
2. Estimated equilibrium generation dose, reached in about 100 years time.	27 mr	
Strontium 90		
1. Mean conc. in air (1952–1955).	$4x10^{-16}\mu c/cc$ ($2x10^{-6}$mpl[1])	1. Mean conc. in drinking water is likely to remain well below that of rainwater because of filtration and absorption by soil.
2. Equilibrium conc. in air (reached in 10 years[2]).	$2.4x10^{-15}\mu c/cc$($1.2x10^{-5}$mpl)	
3. Mean conc. in rain (1952–1955).	1.7 $\mu\mu c$/1 (.002 mpl)	2. Top foot of soil contains about 400 mc/km^2 of Radium 226, an element with similar chemical properties to Strontium.
4. Equilibrium conc. in rain (reached in 10 years).	8.0 $\mu\mu c$/1 (.01 mpl)	
5. Conc. on ground on 1.1.56	4.5 mc/km^2	
6. Max. conc. on ground due to bombs already exploded (this will be reached in 1969 approx.).	14 mc/km^2	
7. Equilibrium value, reached in approximately 100 years time.	200 mc/km^2	

[1] The m. p. l's used are the occupational m. p. l's recommended by the I. C. R. P.

[2] Equilibrium figures are those which will ultimately apply if the present rate of weapon firing continues indefinitely.

ACKNOWLEDGEMENTS

The authors would like to record their gratitude to the Royal Air Force for the part they played in the experimental work, and to Mr. R. G. D. Osmond of the A. E. R. E. outstation at Woolwich who carried out the rediochemical analysis of Sr^{90} in rainwater.

Radiostrontium Fallout in Biological Materials in Britain

By R. J. Bryant, A. C. Chamberlain, A. Morgan, and G. S. Spicer, Chemistry and Health Physics Divisions, A. E. R. E.

1. INTRODUCTION

The general problem of the nature and effects of fallout of radioactivity from nuclear weapon tests has been considered by the Medical Research Council (1956) in Britain and the National Academy of Sciences (1956) in the U. S. Details of the physical geographical and meteorological aspects have been given by Eisenbud and Harley (1953, 1955, 1956) Stewart et al. (1955 & 1956) and Libby (1956). Libby (loc. cit.) and Martell (1955 and 1956) have described the U. S. work on the analysis of Sr^{90} in soils and biological tissues. Booker et al. (1956) have issued a preliminary report on the early results of the British work, and Bryant, Packman and Spicer (1956) have given an outline of the analytical method used at Woolwich for strontium analysis.

A variety of units have been used for reporting fallout data. It is best to use metric units where possible. The specific activity of Sr^{90} relative to calcium is expressed in micromicrocuries Sr^{90} per gram calcium and denoted by the letters S. U. Thus, in soil, vegetation, milk or bone:—

$$1 \text{ S. U.} = 10^{-12} \text{ curies } Sr^{90} \text{ per gram Ca}$$

The following physical data on the long range fallout from tests are relevant to an understanding of the uptake and distribution in biological tissues.

(i) All nuclear explosions produce Sr^{90} together with other fission products. The fission product activity is usually roughly proportional to the power of the explosion. Since Sr^{90} and Sr^{89} have gaseous precursors, they are not necessarily produced in the same physical form as the bulk of the fission product activity, and their distribution as between local and long range fallout may be different.

(ii) The physical form and distribution of the debris depends on the mode of firing and the power. In general, H bomb fission products are distributed in smaller particles, are found higher in the atmosphere, remain there longer and fallout more uniformly over the earth's surface than A bomb fission products.

(iii) The greater part of the cumulative fallout to date (1956) has been due to H bomb tests. The ratio of H to A bomb fallout is higher in the U. K. than the U. S. The ratio will increase in both countries with time, since much of the activity from H bombs already exploded yet remains to fall to earth, having a mean hold-up time in the stratosphere of the order of a decade. Fallout over temperate latitudes in the Northern Hemisphere is grossly uniform except for an excess within a few thousand kilometres distance from test sites.

(iv) Most of the fallout occurs in rain.

2. OBJECTIVES OF PRESENT WORK

Immediate objectives:

(i) Development and verification of accurate and economical analytical methods for low Sr^{90} levels in soils and biological materials.

(ii) Determination of the cumulative deposited activity, by total strontium analysis of soils, for comparison with estimates from rainfall and other methods.

(iii) Determination of current levels in human and animal tissues and food, on a sufficiently wide statitical and geographical basis.

(iv) Observations of the trend of the above with time.

Long term objectives:

(v) Investigation of the natural history of Sr^{90} in soils, and the uptake from soils to plants.

(vi) Investigation of the foliar retention of fallout by plants.

(vii) Investigation of the metabolic chain:—plants—animal tissue—milk—human tissue.

The practical importance of objectives (v) and (vii) is that this information is needed to enable present levels to be extrapolated to future conditions.

8. SAMPLING METHODS

The British sampling was begun in 1954 in consultation with Dr. L. T. Alexander of the U. S. Dept. of Agriculture. The sampling was and largely still is done by the regional staff of the Ministry of Agriculture, Fisheries & Food.

The two most important factors influencing the levels in biological materials were originally thought to be the amount of rainfall, as affecting the total fallout, and the soil conditions, as affecting the uptake from the soil to plants. It was not realised until later that foliar retention of Sr^{90} might be the dominant factor, at least on some soils. It was decided to use the sheep for sampling animal bone, on the grounds of cheapness and range of habitat.

Five farms were chosen, two in Suffolk with low rainfall and calcareous soil, and three in Wales with high rainfall and well leached acid soil. Details of these sites are given in Appendix A1, numbers 1 to 5.

All the farms carried sheep grazing permanent pastures, but the system of management of hill and lowland sheep differs. On the hill farms in summer the animals range over the mountains, where the grazing areas are often small patches of grass on hillsides interspersed with bracken. The mountain pastures are usually not limed, and may be very deficient in calcium. In the winter the sheep may be brought down to the valleys, or sent away to other areas. Some hay or other supplementary feeding may also be given.

The management of lowland sheep is different. Their grazing is usually controlled so that an area is cropped and then left to make new growth. In winter they may be folded over roots or beet tops, or given hay.

It will be seen that the amounts of rainfall, types of soil and systems of grazing the sheep are all interrelated. It will not be possible to ascribe differences in the levels of Sr^{90} in hill and lowland sheep to one factor or the other, until the underlying processes are understood.[1]

The 1954 sampling system called for soil, vegetation and sheep bone samples taken in the spring or summer. The soil samples were in fact taken from the areas grazed by the sheep—in the hill areas from the mountain pastures—but the vegetation was from hay fields. This had two effects.

(a) Hay in Wales is grown in the mountain valleys where the soil is less acid than on the hills, so that the soil conditions were not the same as for the sheep and soil samples.

(b) Hay in Suffolk is exposed to foliar absorption during the whole of the spring growing season (2 to 3 months) whereas the grazing cycle on the pastures is 2 or 3 weeks.

Thus, for different reasons, the hay samples in neither Wales nor Suffolk were representative of what the sheep were eating during the summer.

The difficulties in arranging a simple but representative sampling system are apparent. In the circumstances it is perhaps surprising that the relative activity in British samples (i. e. the ratio of vegetation; sheep bone; milk; human bone) agrees as well as it does with that found elsewhere, (para. 7.6 below).

In the 1956 routine sampling procedure, of which details are given in Appendix A2, the difficulties (a) and (b) above will be overcome by ensuring that the vegetation samples are from the same plots as the soil samples, and that the period of exposure to foliar retention of activity of the samples is similar to that of the actual pasture. It will not however be possible to distinguish the effects of rainfall, soil type, and grazing systems independently.

The decision to take samples from Welsh hill areas has introduced many difficulties, but it has been valuable in throwing up at an early stage the degree of variation in results which must be allowed for in any policy decisions affecting fallout.

Not much progress can be made with the long term objectives of the work until the relative importance of foliar and root uptake is understood. To study this, 4 sampling positions have been selected within 15 miles of Harwell, with approximately the same rainfall, but on differing soil types. At each site grass is cut from the same area every 3 weeks, and the activity compared with the fallout in rain measured over the same period. It is also planned to do growth experiments using soil from these areas. The results from these investigations are not yet complete.

---

[1] Had cattle been used instead of sheep there would have been the same sort of problem, though not perhaps in so acute a form. Milk cattle are rarely nowadays grazed on unimproved soils, but the systems of management differ considerably in different areas. Moreover dairy cows are often given cattle cake or other foods not grown on the farm.

Milk sampling in the U. K. has so far been confined to a regular sample of dried, skimmed milk from a factory at Yeovil, Somerset. Use of factory dried milk has the disadvantage that it is not referable to any particular pasture, but the advantage that the bulking process smooths out variations from farm to farm. The samples are now being extended to other areas.

4. ANALYTICAL METHODS

4.1 *Methods used in Woolwich laboratories of Chemistry Division A. E. R. E.*—All methods ultimately depend on the separation of active strontium, with added carrier, as nitrate in strong nitric acid solution and include ferric hydroxide and barium chromate scavenges to remove contaminating activities. The separated strontium is stored in the presence of yttrium carrier for at least 14 days and the yttrium precipitated as hydroxide. The yttrium hydroxide is then converted to oxalate for mounting and counting.

Strontium is precipitated as carbonate, mounted and counted after allowing the yttrium to grow in again.

The method described above can be applied directly to bone ashes but for hay and vegetation ash and soil the initial concentration of the calcium and strontium in a suitable form (carbonates or phosphates) is necessary.

Full details of the methods are given in Appendix B.

Appendix B1. The determination of radiostrontium in soil by hydrochloric acid extraction.—This method is aimed at determining the total activity and carrier is therefore added at the extraction stage. The original work was done using 3M acid but 6M is now preferred. Using 3M acid, extraction of calcium tended to be low in some cases although there is no evidence that the total activity was not determined.

Calcium and strontium are precipitated as oxalates from the extract, any iron and aluminum removed as hydroxides and the calcium and strontium finally precipitated as carbonates to which the nitric acid method is applied.

Appendix B2. The determination in soil by fusion with sodium hydroxide and sodium carbonate.—Initial attack with sodium hydroxide and subsequent addition of sodium carbonate is preferred to fusion with sodium carbonate alone as a lower temperature can be used, the attack on the crucible is less and the melt readily disintegrates in water. After removal of silica from the insoluble carbonates, the method is essentially similar to that applied to the acid extract. Carrier is added to the soil before fusion. The maximum amount of sample which can be conveniently dealt with by this method is 100 gm. whereas 500 gm. can be used in the acid extraction.

Appendix B3. The determination in soil by ammonium acetate extraction.—As the aim here is to determine strontium available to the plant, carrier is not added until the extract is separated from the soil. Calcium and strontium are precipitated as carbonates which are treated as in the acid extraction method.

Appendices B4 and 5. The determination in animal and human bone ashes.—The nitric acid separation is applied directly. In the case of human bones where the amount of sample is limited and the activity low it is impracticable to measure the separated yttrium and the strontium + yttrium count is used. In a few favourable instances it has been possible to check the accuracy of this procedure by counting the separated yttrium.

Appendix B6. The determination in dried milk.—Direct application of the nitric acid separation usually gives low strontium yields. The calcium and strontium carrier are therefore concentrated by an initial phosphate precipitation.

Appendix B7. The determination in vegetable ash.—The ash is treated for the removal of silica and calcium and strontium precipitated as phosphates before the application of the nitric acid method.

Chemical yields for strontium vary from 60–80% for bone, vegetable and milk ashes and high calcium soils and from 40–60% for low calcium soils.

The yttrium yields are about 95%.

Work on this project is done in laboratories remote from others dealing with activity and specially reserved for this purpose. Frequent blanks are carried through the procedures to check the reagents, carriers etc.

All results obtained using these methods in the Woolwich laboratories of Chemistry Division will be described as Woolwich (or W) results.

4.2 *Analytical Methods used in the Health Physics Laboratory, A. E. R. E. Harwell.*—In this laboratory the determination of radiostrontium is at present confined to vegetation, animal bone and milk samples.

The chemical methods used are based on the same principles as those used at the Woolwich Outstation and only differ in minor details. They are described briefly below:

(a) The determination in ashed vegetation.

The calcium and strontium are extracted from the ashed vegetation by three successive leachings with hot 6M hydrochloric acid. The iron and aluminum are removed from the combined leachings as the hydroxides, after which the calcium and strontium are precipitated as the carbonates and purified by precipitation. Strontium carrier is added to the purified carbonates before the fuming nitric acid separation of strontium from calcium. Subsequently other radio isotopes are removed by barium chromate and yttrium hydroxide scavenges and the purified strontium stored with yttrium carrier for 18 days. Finally the yttrium is separated, mounted as the oxalate and the decay followed. The strontium is precipitated as the carbonate, weighed, mounted and the decay followed after the yttrium has grown in, in order to determine the $strontium^{89}$.

(b) The determination in bone ash and milk ash.

These are both treated in the same way and after the addition of strontium carrier, the fuming nitric acid procedure is applied directly. Otherwise the methods are identical with that for ashed vegetation.

The counting methods are identical with those used by the Woolwich Laboratories and described in the next section.

The counters were calibrated independently and interchange of sources with Woolwich has shown good agreement.

5. COUNTING METHODS (WOOLWICH LABORATORY)

Precipitates for counting are filtered on 2.1 cm. filter papers in perspex filter holders. After suitable washing and drying the papers are mounted on aluminium trays using a dilute solution of Gelva (polyvinyl acetate resin).

Three types of counter are in use.

(a) An anti-coincidence set-up with special low background G.M.4. counting tubes (7mgm/cm^2 window) surrounded by a complete ring of 9 Type G.E.21 brass bodied guard tubes. The assembly is shielded by 4 inches of steel and the background is 0.4–0.5 cpm. depending on the G.M.4. tube. The total, coincidence and anti-coincidence counts are scaled and the accuracy of the anti-coincidence count is thus continuously monitored. The efficiency for counting Y^{90} with 25 mgm. sources is about 25%.

(b) Three position anti-coincidence counters in which the background and two samples can be measured. These are normally set to count one hour in each position and the individual hourly counts and total counts from each position are recorded. The counting tubes are either E.H.M.2 (2 mgm/cm^2 window) or special G.M.4 tubes with 13 Type G.M.5 glass envelope guard tubes arranged at 180°. The assemblies are shielded by 2 inches of lead and normal backgrounds and efficiencies for Y^{90} counting are

E.H.M.2	1.5–2.0 cpm.	efficiency c. 30%
G.M.4	1.0–1.3 cpm.	efficiency c. 25%

(c) Standard counting arrangement using E.H.M.2 counting tubes and 2 inch lead shield with a background of 7 cpm. The efficiency is about 20% and this set up has been modified to permit the direct counting of bone ashes.

Type (b) is used for most of the work, type (a) being reserved for the lowest activities and type (c) for the more active animal bones.

The counters are calibrated using virtually carrier free solutions standardised by the Isotope Division, A. E. R. E. Suitable aliquots are taken, and precipitated with appropriate amounts of carrier, mounted and counted. From these results efficiency versus source weight tables (or curves) can be prepared which are used in converting cpm. to dpm.

When significant amounts of $strontium^{89}$ are present the $Sr^{90}+Y^{90}$ contribution in a mixed $Sr^{89}+Sr^{90}+Y^{90}$ source is calculated from the Y^{90} count and the Sr^{89} count obtained by difference.

With the exception of the results for human bones, the $strontium^{90}$ content is based on the counting of the $yttrium^{90}$ source, the radiochemical purity of which is checked by following its decay. The decay of the mixed strontium and yttrium sources is also checked.

6. INTERCOMPARISON SAMPLES EXCHANGED WITH U. S.

6.1 *Bone ash samples sent to U. S.*—U. K. sheep bone ash samples, from yearling animals killed in the spring of 1955 were sent to U. S. and analysed at Chicago. Results of three laboratories (two U. K. and one U. S.) are as follows, expressed in S. U.

TABLE I.—*Intercomparison of U. K. bone ash*

U. K. Ref	A. E. R. E. results		U. S. results [1]
	Harwell	Woolwich	
B3	3.0	13	31.4
B4	12.7	15	13.1
B5	5.7	5.7	5.2
B6	56	59	60.6
B7	13.4	17	18.3

[1] Martell (1955). These results are also given in Libby (1956) figure 3b, but are there wrongly ascribed to 1954;

Agreement is good, except for one sample.

6.2 *Intercomparison samples suplied by Health & Safety Laboratory, New York.*—Samples of sheep bone, hay and milk ash, and also of soil, collected from the New York area in September/October 1955, have been analysed by the A. E. R. E. (Woolwich Outstation) New York, Chicago and Pittsburgh laboratories as follows, results being in S. U.

TABLE II.—*Intercomparison of HASL samples*

	Woolwich	New York	Chicago	Pittsburgh
Sheepbone	5.6	5.8	4.45	6.98
	5.6	5.1	5.14	4.45
Hay	19.5	20		19.7
	19.8			17.9
Milk	3.1	3.3	2.4	2.4
	3.0	3.1		2.6

Agreement on the bone, hay and milk samples is excellent, especially between the Woolwich and New York laboratories.

On the soil sample, Woolwich have given results as follows but results from the other laboratories have not yet been received.

TABLE III.—*Woolwich results on HASL soil cample*

Initial attack	Sample weight	%Ca	Sr^{90} activity		S. U.
			dpm/ft^2	$\mu\mu c/m^2$	
$NaOH+Na_2CO_3$ fusion	100 gm	0.39	620	3050	17.3
2×500 ml. 3M HCl	200 gm	0.28	640	3150	25
	400 gm	0.24	580	2850	26

7. RESULTS ON U. K. SAMPLES

A check list of results on all British samples on which analysis is complete (whether analysed in the U. K. or the U. S.) is given in Appendix C.

7.1 *Soils.*—The 1955 soil samples have been analysed at Woolwich, by three methods, ammonium acetate extraction, hydrochloric acid extraction, and fusion with sodium carbonate. The agreement on total Sr^{90} between the last two methods is very fair, taking into account the low specific activity (20 to 50 dpm/kg soil) and the presence of some activity in particulate form, which makes it difficult to ensure that samples are representative.

There seems to be significantly more total Sr^{90} in the top 4″ of the Vyrnwy and Cwmystwyth soils than in those from the Suffolk stations. This may well be associated with the high rainfall (see Appendix A), but it must not be forgotten that these soils are very well leached. Stewart et al (1956) have measured the Sr^{90} fallout in rain at Milford Haven, Pembrokeshire over 3 weekly periods since the spring of 1954. Without assuming anything about the absolute levels found, their curve can be used to normalise soil estimates at different dates in 1955 to a fixed date which will be taken as 1st October, 1955. The U. K. soils were sampled in late March and early April. The factor of increase on Stewart's curve between 1st April and 1st October is 1.5. In Table I the results of the 1955 U. K. soil samples (fusion and HCl results averaged) from Appendix Cl are multiplied by the factor 1.5 and compared with three sets of results on U. S. soils, namely:—

(i) The soil taken at Ithaca N. Y. in September, 1955, depth 0–2″, by HASL for intercomparison purposes. The Woolwich results on aliquots of this soil were given in para 6.2 above.

(ii) The 17 U. S. soils (0–2″) sampled between 23rd September and 20th October, 1955 and analysed for Sr^{90} by HCl extraction by Hardy and Morse (Libby, 1956, Table 6). The mean of these samples was 2800$\mu\mu$c/m^2 (578 dpm/ft^2) and the two New York samples among them averaged 2200$\mu\mu$c/m^2 (450 dpm/ft^2).

(iii) The 6 Illinois/Wisconsin soils sampled by Alexander in late September 1955, extracted with ammonium acetate at Beltsville and analysed by Martell (1956) with mean Sr^{90} activity of 4800±900$\mu\mu$c/m^2 (970±180 dpm/ft^2). These soils were sampled to depth 8″, 80% of the activity being found in the top 2″ of unploughed soil.

TABLE IV.—*Sr^{90} in soils at 1st October 1955*

	Annual rainfall (inches)	Soil depth	Sr^{90} activity	
			$\mu\mu$c/m^2	mc/mile^2
U. K. Measurements:				
Cwmystwyth & Vyrnwy	80	0–4″	4000	10.0
Talgarth	35	0–4″	2500	6.5
Suffolk	25	0–4″	1300	3.3
Ithaca, N. Y.	42	0–2″	3070	8.0
U. S. Measurements:				
U. S. (av)	------------	0–2″	2800	7.2
New York	42	0–2″	2200	5.7
Wis/Ill	33	0–8″	4800	12.4

There is good agreement between the total Sr^{90} in the top 4″ of Cwmystwyth and Vyrnwy soils and the absolute value of the cumulative rainfall activity at Milford Haven, Pembrokeshire. Stewart et al (1956), give the total corresponding to 1st October 1955, as 4100 $\mu\mu$c/m^2 (10.5 mc/mile^2). However, the profile of Sr^{90} activity in the Welsh soils is so far unknown, and too much reliance cannot be placed on this comparison.

7.2 *Vegetation Samples.*—The results are given in Appendix C2. To express the results in S. U. ($\mu\mu$c/Sr^{90} per gram Ca) is appropriate as long as uptake from the soil is considered the major mode of contamination. When foliar retention is considered $\mu\mu$c/kg or $\mu\mu$c/m^2 of ground are sometimes more helpful units.

The notable feature of the 1955 samples (D4 to D13 and D20) was the uniformity of the results as between samples, despite the widely varying geographical and soil status of the sites. With two exceptions, all lay in the range 25 to 53 S. U. All were mature hay samples and therefore all had approximately the same period of growth and exposure to fallout.

The five samples D14a to D18/2 were taken at Chilton, Berkshire, where the soil is very calcareous (circa 100 grms, Ca per kg. soil). Rough grass, some of it dead, was collected from an ungrazed area of the former airfield. The activity ranged from 24 to 64 S. U. as compared with a S. U. value in the soil of about 0.2, thus strongly suggesting foliar retention on the dominant mode. About 25 percent of the vegetation activity was removable by washing with distilled water. Expressed per unit area of ground, these samples ranged from 50 to 85 $\mu\mu$c/m^2. From the rainfall measurements of Stewart et al (1956) the rate of fallout of

Sr^{90} during the early spring of 1956 was about 200 $\mu\mu c/m^2$/month. The Chilton results could therefore be explained without reference to soil uptake if, for example, 25% of the fallout was retained on the leaves for an average period of about 6 weeks.

Samples D24A and D25A were taken at similar airfield sites after the new season's growth of grass was available. The levels in terms of S. U. are a little lower than those of the preceding samples. In terms of $\mu\mu c$/kg and $\mu\mu c/m^2$ they are considerably lower, reflecting the lower calcium content of the spring flush of grass.

Samples D21 and D22 were taken at Cwmystwyth from a hillside sheep run similar to that on which the sheep B6 and B10 had grazed. The season was late, and the grass sparse. The activities of 370 and 510 S. U. found in the grass are in about the same ratio of 10:1 to the general level at that time as were the sheep bones taken in 1955 from Cwmystwyth to the general level in sheep bones.

7.3 *Sheep bones.*—The results of Sr^{90} analysis on 21 long bones from British sheep are given in Appendix C3.

The results for lowland sheep in 1955 and early 1956 were fairly uniform, the range of 8 samples being from 7.5 to 15.4 S. U. and the median 14 S. U. This compares with 15 S. U. estimated by Martell (1956) for the Chicago area in late 1955.

With hill sheep the results are more variable, levels as high as 59 and 183 S. U. (Cwmystwyth) 35 S. U. (Welshpool) and 65 S. U. (Haslingden) having been found. As shown in the section on sampling, it is not yet possible to say what weight to attach to excess rainfall, soil type or grazing habits in contributing to these results.

7.4 *Milks.*—Seven samples of dried milk made at a factory at Yeovil, Somerset, during the period March-July, 1955 have been analysed at the Health and Safety Laboratory, New York Operations Office, AEC, through the kindness of Dr. J. H. Harley. The mean level was 3.2 S. U. and this compares with means of 2.5 and 3.3. S. U. respectively for New York and Chicago milks over the same period as deduced from Libby (1956, Figure 1c). Similar samples dated April, 1955 and March 1956 respectively analysed at Harwell gave 4.3 and 3.8 S. U.

In samples from all three localities (New York, Chicago and Yeovil) there is evidence of a peak of Sr^{90} activity in May and June 1955 (fig. 1). Fallout was relatively heavy about this time, and the effect of this may have been accentuated by the change in the feed of the cows from hay and similar stored foods to open grazing at that time of year.

7.5 *Human bones.*—28 British human bone samples dating from October 1955 to February 1956 have analysed at Woolwich to date. Details are given in Appendix C5 and a graph of activity against age at death in Fig. 2.

The earlier samples were mostly ribs, but in future femurs will be used whenever possible. Geographically the samples are mainly from the Midlands and South East of England, with a few from Carlisle to represent the West Coast.

The highest value found so far is 1.3 S. U. in an eleven weeks old child (Carlisle), closely followed by 1.2 and 1.1 S. U. in two Birmingham one year olds, and 1.05 S. U. in a 3½ year old from Dudley. Bones from one stillborn infant have been analysed, and gave 0.45 S. U.

Adult bones show consistently low values of 0.2 S. U. or less. Much of the calcium in adult bones was of course laid down before fallout became significant.

The range of levels in British bones is almost indistinguishable from that found in the U. S. and reported by Libby (1956). The maximum in his series is 1.7 S. U. with several others just over 1 S. U. Two 1955 stillbirths from New England show 0.4 and 0.5 S. U.

7.6 *Relative levels in vegetation, bone and milk.*—The results of three series of samples are given below, median values being given except for the child, for which the maximum is used. For comparative purposes the results have been normalised to make the vegetation level equal 100, but the results in S. U. are also given in parentheses.

The three series are:

(1) U. S. results of October 1953, as given in Table I and II of Bugher (1955) and in Table 1 of Libby (1956).

(2) U. K. results of 1955

(3) The New York samples of September/October 1955, referred to in paragraph 6.2 above, with human bone results from Libby (1956).

Also for comparison, experimental results of Comar (1956) are included.

TABLE V.—*Relative Sr^{90}/Ca ratios normalised to vegetation=100*

[S. U. values in parentheses]

	Vegetation	Animal bone	Milk	Child (max.)	Stillbirth
(1) U. S. 1953	100	30	16	8	1.4
	(9)	(2.7)	(1.4)	(0.7)	(0.13)
(2) U. S. 1955	100	28	15	8.5	2.0
	(20)	(5.6)	(3.0)	(1.7)	(0.4)
(3) U. K. 1955	100	40	9	3.7	1.3
	(35)	(14)	(3.3)	(1.3)	(0.45)
Comar (exptl)	100	37	13		

8. SUMMARY AND CONCLUSION

The good agreement between independent determinations by different laboratories (paragraph 6) shows that the analytical methods of determining Sr^{90} in biological materials are adequate. The error is small in comparison with the biological variations between samples.

The soil determinations cannot yet be considered final, but it is unlikely that the estimation of total Sr^{90} by the hydrochloric acid and fusion methods is seriously in error.

There is good evidence that from the spring of 1955 onwards the levels of Sr^{90} in biological materials in the U. K. and the U. S. have been similar. This is particularly true of milk samples and human bones, but appears also in the results for animal bone and vegetation.

As Libby (1956) has stated:

"A Sr^{90} fallout probably derived from megaton weapons and nearly uniform over the world, except for local effects due to rainfall variations and to fallout from submegaton weapons, seems clearly established."

9. ACKNOWLEDGEMENTS

We are greatly indebted to Mr. K. H. Jones and all the members of the staff of the Ministry of Agriculture, Fisheries & Food who have helped in the collection of samples for this work. In particular Dr. Rice Williams and Mr. T. H. Caldwell have given most helpful advice and have provided invaluable assistance in arranging subsidiary experiments.

APPENDIX A1

Principal U. K. sampling sites

No.	Site	Soil	Total Ca in soil gms/kg dry wt.	Altitude (feet)	Annual rainfall (inches)
1	Earl Soham Suffolk	Boulder clay	16	90	25
2	Boulge Suffolk	Sandy clay loam	3	120	25
3	Talgarth Brecon	Free draining soil on old red sandstone	2.5	1,050	35
4	Cwmystwyth Cardigan	Peat on shale (free draining)	0.3	1,200	80
5	Vyrnwy Montgomery	Peat on shale (free draining)	2	1,100	78
6	Boxworth Cambridge	Dark brown loam with chalk particles		157	20
7	Norwich Norfolk	Sandy loam with gravel		85	25
8	Princetown Devon	Sandy peat on granite		1,300	85
9	Rookhope Durham	Peaty sandy loam with podsol		1,600	56

NOTE.—All these farms carry sheep on permanent pastures. Nos. 1 to 5 were the original (1954) sites. From 1956 onwards Nos. 4 to 9 will be used, supplemented with additional samples as required.

APPENDIX A2

DETAILING OF SAMPLING PROCEDURE

1. Soil and vegetation

Samples or herbage and soil will be taken in the first fortnight of July each year, beginning in 1956. Half acre sites will be used on the chosen sampling farms, the same half acre being used each year.

Grass.—On the half acre, 10 plots, as near to one square yard as possible will be selected. The grass from each of the 10 plots will be cut with shears to about "lawn-mower" length, i. e. short enough to get the vegetation that a sheep would graze but long enough to avoid contaminating the grass sample with soil. The grass from the 10 sites will be bulked. If the bulk sample falls appreciably below 5 lbs. in weight, more yard plots will be cut, the total number being recorded.

Mat.—After the grass has been cut, a core of any grass mat there might be present will be taken from each of 10 plots, and bulked. A sampling tool will be used giving a 4'' diameter core.

Soil.—A 4'' deep core of soil will be taken from the spot where the mat had been removed. In practice, a core of mat and soil exceeding 4'' in depth may be taken, the mat removed and kept separate and the top 4'' of the core retained as the soil sample. The sample from the 10 plots may be bulked. The exact surface area must be noted.

In each future year, new square yard plots as near as possible to the original plots, but not overlapping them, should be chosen.

2. Sheep

The sheep to be taken should be in the region of 15 months old. It will have to be accepted that some sheep would spend part of their lives on pastures possibly remote from the sampling site. It is important, however, that the sheep should have spent at least the last few months in grazing pastures on or near the sampling site. Long bones only will be required.

Bones should be cleared of surface meat but need not be otherwise treated.

3. Other information

Samplers will be asked to provide:

(a) Details of terrain, rainfall, etc.

(b) Details of sheep management (i. e. whether sheep had grazed in sampling pasture continuously, and breed).

(c) Photographs of the site, and a "close-up" of the herbage.

4. Other matters

(a) Reasonably level plots should be chosen for herbage and soil samples.

(b) The plots need not be fenced off in any way unless the yield of grass per square yard is likely to be less than ½ lb. In any case, cages should not be put in position more than 3 weeks before the sampling.

(c) Sites should remain unploughed for at least 5 years.

ATOMIC ENERGY RESEARCH ESTABLISHMENT

Radiostrontium and Radiocaesium Measurement in Biological Materials to December 1956

By D. V. Booker, F. J. Bryant, A. C. Chamberlain, A. Morgan, and G. S. Spicer

1. INTRODUCTION

The methods used in the estimation of Sr.90 in biological materials, the intercomparison of results between different laboratories and the results up to the early part of 1956 were fully described in A. E. R. E. HP/R 2056.[1] The present report gives further results for Sr.90, presents some data on Cs.137 in milk, and examines in greater detail the evidence for the trend of radioactive contamination with time.

2. SR.90 IN SOIL

An effort was made to get a reliable estimate of the total Sr.90 in soil, for comparison with the rain data of Stewart et al (1956).

Three soil horizons (0–4″, 4–8″ and 8–12″) were taken in July, 1956, at each of four sites within 15 miles of Harwell, but on widely differing soil types as follows:

Site	Soil	Annual Rainfall (inches)
Grove, Berks	Clay	27.5
Aldermaston, Berks	Acid sand	27.5
Culham, Oxon	Greensand	25
Chilton, Berks	Chalk	27.5

The soils were extracted with 6M hydrochloric acid at Woolwich. This method has been shown to remove as much Sr. 90 as it got by complete fusion of the soil (HP/R 2056). The results are given in Table I.

TABLE I.—*Sr. 90 in soil (July 1956)*

Ref.	Site	Depth	gms. Ca/kg.	$\mu\mu c/m^2$	S. U.
UK36	Aldermaston	0–4″	1.60	2560	18.6
	Aldermaston	4–8″	1.52	<150	<0.8
	Aldermaston	8–12″	1.46	<50	<0.3
UK37	Culham	0–4″	3.00	2530	8.0
	Culham	4–8″	2.68	220	0.6
	Culham	8–12″	3.46	<150	<0.3
UK35	Grove	0–4″	39	1900	0.66
	Grove	4–8″	17	270	0.18
	Grove	8–12″	10	224	0.22
UK38	Chilton	0–4″	156	2180	0.15
	Chilton	4–8″	185	<150	<0.01
	Chilton	8–12″	204	<150	<0.01

Where the sign < is used, the activity was less than the minimum measurable.

The following deductions may be drawn:

(a) at least 80 per cent of the activity is in the top 4″.

(b) There is good agreement in total Sr. 90 between sites. The nature of the soil does not seem to affect the degree of retention of the fallout.

(c) The average level in this area is 2.5 mc/km^2 (6.5 mc/mi^2).

[1] Circulated to the October 1956 meeting of the United Nations Scientific Committee on the Effects of Radiation with reference A/AC82/G/R30.

3. SR. 90 AND CS. 137 IN MILK

The regular supply of skimmed dried milk from a factory at Frome, Somerset[3] has continued. Some of the samples have been analysed at the Health and Safety Laboratory at New York, through the help of Dr. J. H. Harley, and some done at Harwell or Woolwich. In fig. 1a the results are shown in terms of the specific activity of Sr. 90 relative to calcium, using the unit referred to as the strontium unit.

One strontium unit (S. U.) = One micro-micro-curie Sr. 90 per gram of calcium.

Also in fig. 1a is drawn the graph of cumulative Sr. 90 fallout in rain at Milford Haven, Pembrokeshire, given by Stewart et al (1956). The units are millicuries Sr. 90 per square kilometre. The trend of the figures with time is discussed below in para 6.

In fig. 1b is shown the Cs 137 activity of samples from the same series. The Harwell results were obtained by gamma spectrometry of the dried milk, whereas the Woolwich results were by chemical analysis. The details of the gamma spectrometric method are given by Booker (1957).

A series of samples of full cream dried milk from different regions in the U. K. was taken in October, 1956. The results of Sr. 90 and Cs. 137 analysis on these samples are given in Table II.

TABLE II.—*Sr–50 and Cs–137 in milk (October 1956)*

Area	Sr–90 μμc/gm. Ca.	Cs–137 μμc/gm. K
Somerset	4.6	28
Yorkshire	4.3	30
Cumberland	6.5	28
Carmarthen	8.0	65
Antrim	6.9	87
Londonderry	10.3	84

Calcium is about 1.2% and potassium 1.4% of dried milk by weight.

The Sr. 90 activity of 10.3 S. U. in milk from County Londonderry is similar to maxima of 10 or just over found in the U. S. (Harley et al 1956) and in Canada (Canadian submission to U. N. of October, 1956).

4. SR. 90 IN SHEEP BONES

Yearling sheep have been taken from three areas in Wales in each of the years 1954, 5 and 6. The sheep came from the same flocks each year, and the flocks were grazing the same pasture. The areas covered by hill sheep are large, and the exact soil conditions cannot be specified, but analysis of samples showed that the soil was calcium deficient, especially at Cwmystwyth (HP/R 2056, Appendix A1)

The results of Sr. 90 analysis on the long bones of these sheep are given in Table III, and shown graphically in fig. 2.

TABLE III.—*Sr. 90 in bones of Welsh sheep (S. U.)*

	Cwmystwyth Cardigan	Vyrnwy Montgomery	Talgarth Brecon
1954	18.8	7.7	1.5
1955	59, 56	17, 13	5.7, 5.7
1956	170, 151	42, 40	24, 24

The 1954 analyses were done in the U. S. Those of 1955 and 1956 have been done at Woolwich and Harwell independently, and in Table III the results of both analyses are given (Woolwich in the left).

[3] The location was wrongly referred to as Yeovil, Somerset in HP/R 2056, but the milk processed at the factory is in fact drawn from an area of 20 miles radius round it.

In fig. 2 the cumulative fallout of Sr.90 in rain is also given (this time on a log scale). It appears that the rate of increase of Sr.90 activity in these sheep has been approximately exponential, with an average increase of a factor 3 per annum, and has been about as rapid as the rate of increase of cumulative fallout.

Bones fro 10 English sheep killed in 1956 have been analysed for Sr.90. Three hill sheep from Dartmoor, Durham and Lancashire gave 53, 71 and 61 S. U. respectively, showing that the relatively high levels are not confined to limited areas in Wales. Seven lowland sheep from south and east England showed Sr.90 activity ranging from 7.8 to 15.6 S. U. Direct comparison with previous years was not possible, because the Suffolk flocks from which the 1954 and 1955 animals were obtained have been broken up, but the general level in lowland sheep seems little altered in 1956 compared with 1955.

5. SR.90 IN HUMAN BONES

Analyses of 21 bones additional to those reported in HP/R 2056 have been completed and the results are given in Table IV. Work has been concentrated on the bones (femurs) of children, since previously it had been shown that they show higher activity than those of adults. The ages at death ranged from 2 days to 14 years. 12 specimens from infants under one year of age averaged 0.62 S. U., 5 from children of 1 to 4 years averaged 0.76 S. U. and 4 from children of 7 to 14 years 0.27 S. U.

Three specimens, all from 6 month old infants, showed Sr.90 activity of 1 S. U. or greater, but none exceeded the previous maximum of 1.3 S. U. reported in HP/R 2056.

The femur HB38 from a 14 year old boy was divided into four parts transversely before analysis. The epiphyseal bone at either end showed double the specific activity of the centre of the shaft. This was to be expected since recently deposited calcium contains more Sr.90 than that laid down several years ago.

TABLE IV.—*Sr-90 in human femurs (additional to those given in Appendix C4 of HP/R 2056)*

Ref	Date	Age at death	District	Sr-90 (S. U.)	Notes
32	5/56	1 m	Herts	0.5	
33	4/56	2 m	Sussex	.15	
34	6/56	17 m	Surrey	.9

51	7/56	3½ y	Sussex	.64	
52	6/56	7½ y	Essex	.38	

6. TREND OF RESULTS WITH TIME

It would be valuable if the rate of increase of Sr. 90 and Cs. 137 activity in biological materials could be correlated with the physical data on fallout rates. The following indications emerge from the data:

(i) *Milk.*—There was a sudden rise in activity in the Spring of 1955 . This appears in Sr. 90 estimates in British and American data (cf. HP/R 2056, fig. 1) and applies to Cs. 137 as well as Sr. 90. This rise was probably due to a combination of two factors.

(a) An increase in the rate of fallout at that time, which is noticeable as a temporary increase in the slope of Stewart's grapt reproduced in fig. 1a.

(b) The sending out to pasture at that time of year of cows which had been given stored feed during the winter.

Since the summer of 1955 the milk levels seem to have been rather steady both in U. K. (fig. 1) and in U. S. (Eisenbud, 1957); and the spring increase was not nearly so marked in 1956 as in 1955. The median of 9 Somerset samples in 1956 is 4.2 S. U. as compared with 4.1 S. U. for 13 1955 samples.

(ii) *Sheep bones.*—There is a sharp distinction in the U. K. results between hill sheep and lowland sheep. The Sr. 90 level in the bones of the Welsh sheep seems to be increasing about as rapidly as the cumulative fallout whereas animals from S. E. England show little increase in the period 1955–1956.

(iii) *Human bones.*—Samples are too limited in number and diverse in origin to allow of satisfactory comparison, but there is no evidence of a rapid increase of Sr. 90 activity in the last year. A considerable time lag between changes in the environment and in human bone must be expected.

The tentative conclusion from the results so far is that Sr. 90 activity of tissues deriving their calcium from normal soils is increasing less rapidly than the cumulative fallout, and is probably more nearly proportional to the rate of fall-out. On very deficient soils the opposite apears to be true.

These effects may well be correlated with the importance on very low calcium soils of the root as compared with the foliar method of uptake of radiostrontium to vegetation.

7. SUMMARY OF 1956 RESULTS

The range of 1956 Sr. 90 results, and the median values are given in Table V.

TABLE V.—*Sr–90 in biological materials in 1956*

Material	No. of Samples	Sr. 90 activity (S. U.)		
		Max.	Min.	Median
Grass (acid hill soils)	9	2,180	113	370
Grass (normal soils)	27	85	23	40
Sheep bones (hills)	6	170	24	57
Sheep bones (lowlands)	7	15.6	7.8	13.7
Milk (Somerset)	9	5.7	2.9	4.2
Milk (other areas)	5	10.3	4.3	6.9
Human bones (child)	31	1.3	0.15	0.55
Human bones (adult)	8	0.25	0.06	0.20

The details of all the above samples have been given in HP/R 2056 or the present report, except for the grass samples, which will be reported more fully elsewhere.

8. ACKNOWLEDGEMENTS

We are greatly indepted to Mr. K. H. Jones and to the members of the National Agricultural Advisory Service of the Ministry of Agriculture Fisheries & Food for their help in arranging the agricultural samples. We are also greatly indebted to Dr. M. Bodian who obtained the human bone specimens for us.

APPENDIX 3

A REPORT BY THE WORLD HEALTH ORGANIZATION ON GENETIC EFFECTS OF RADIATION

[World Health Organization, Division of Public Information, Press Release WHO/11, March 13, 1957]

GENETIC EFFECTS OF RADIATION

WHO TO PUBLISH REPORT

Throughout man's existence on earth, he has been continuously bombarded by radiations coming from outer space, from radioactive material in the earth's crust, and from natural radioactive elements within his own bone and flesh.

The intensity of this bombardment is being notably increased, in our days, by man-made sources such as medical X-ray machines, radioactive material used in medicine, and also certain material and apparatus used in science, industry and commerce; artificial radioactive elements distributed by man in nature; and, to a minor extent, shoe-fitting machines, radioactive luminous compounds on watches, etc.

Radiation has been demonstrated to be one of the agents which produces genetic mutation in a wide range of organisms from bacteria to mammals, and a Group of 20 international experts was therefore brought together by the World Health Organization (WHO) in Copenhagen last August to discuss research problems connected with the effect of radiation on human heredity.

This Group has produced a highly technical report which, together with a number of specialized papers prepared by certain of its members, is to be published by the World Health Organization within a few months. Advance copies of the text are at present in the hands of members of the United Nations Scientific Committee on the Effects of Atomic Radiation.

"Man's most unique and precious possession is his hereditary material which must determine the health and orderly development of future generations", states the introduction to the Group's report. It goes on, "This Group is of the opinion that the well-being of the descendants of the present generation is threatened by developments in the use of nuclear energy and of sources of radiation."

The report states categorically that "additional mutation produced in man will be harmful to individuals and their descendants * * *" and that " * * * all man-made radiation must be regarded as harmful to man from the genetic point of view".

Gaps in knowledge

The WHO experts agreed that present developments in the peaceful use of nuclear energy should contribute much to man's social and cultural development, and that therefore some risk must be accepted. They recognize, however, that if the dangers are to be minimized, "every possible step must be taken to reduce the exposure of man to radiations, and to understand the effects of exposure * * * Only in the light of more knowledge can decisions be taken to define more accurately the maximum amount of exposure which may be accepted by individuals and populations without risk of serious harm." The Group therefore examined some of the "larger gaps in knowledge" as they appeared at the present time, and listed some thirteen fields of genetic research in which the need for further investigation is urgent.

Cumulative effect

There are strong grounds for believing that inherited effects of radiation are additive, the experts agreed. A small amount of radiation received by each of a large number of individuals can therefore do an appreciable amount of damage to the population as a whole, although the effects may not appear for a number of generations. It is therefore desirable to limit the accumulated radiation doses received by the sex glands of individual men and women, particularly up to 30 years of age, in order to keep the average dose to the sex glands of the population as whole very low.

The most important sources of radiation to the human sex glands, the experts agreed, are at the present time from the natural radiation (normal level between 2 and 5 roentgens per individual in 30 years) and from the radiation received by patients undergoing medical X-ray examination (probable average in certain countries between 1 and 3 roentgens per individual in 30 years). If exposure during therapeutic X-ray treatment is also considered, the "total" exposure to a population might be greater. It is however difficult, the report states, to get sound data for estimating how much radiation due to therapeutic exposures is received by persons before the age at which procreation may be expected to be ended.

In connexion with the danger of radiation from medical sources, one member of the Group pointed out in a paper that radioscopic apparatus, sometimes not adequately shielded, is to be found more and more frequently in the consulting rooms of general practitioners who do not have the necessary formal training in radiology.

Artificial radioactive elements distributed in nature

In a paper by Professor R. M. Sievert, of the Institute of Radiophysics, Stockholm (Sweden), which accompanies the report, some reference is made to artificial radioactive products distributed in nature as a result of military tests. Professor Sievert recognizes that the WHO Study Group was concerned with the peaceful use of atomic energy and the effects, for instance, of the future disposal of radioactive wastes from such peaceful uses.

He points out, however, that it is essential to take into consideration the evidence obtained following atomic weapon tests, since such information is the best at present available for the study of problems in the field of artificial radioactive elements distributed in nature.

Recent measurements from large samples of foodstuffs in Sweden, Professor Sievert says, have shown that foods such as milk, beef, corn and vegetables eaten today contain artificial radioactive elements with a radiation level in many cases exceeding that due to the naturally-occurring radioactive constituents of animals and plants. It does not yet seem possible, Professor Sievert goes on, to estimate the radiation doses to human tissues, nor their distribution in time, which are necessary data for drawing conclusions of biological significance.

Professor Sievert believes that it is extremely difficult to predict what will in the future be the most important sources of radiation from artificial radioactive elements distributed in nature.

"There is reason to believe that the problems of disposal of radioactive wastes will be satisfactorily solved and that precautions in the handling and use of radioactive material will be adequate", Professor Sievert says, but goes on to warn that "accidents and unforeseen events may gradually spread radioactive substances beyond control; they could then follow unknown paths and be harmful to mankind in ways that would become known to us only after long experience."

Some conclusions

In a section entitled "Some Conclusions" the Group's report lists eight recommendations, including the establishment of more institutions and large university departments concerned with human genetics and improved teaching in this branch; the systematic registration of serious hereditary diseases; and efforts by UN Agencies toward the collection and publication of information on subjects like fertility, consanguineous marriages and parental ages which are so essential as brackground in human biological studies.

The Group was particularly impressed with the genetic hazards of man-made radiation from sources used in medicine, industry, commerce and experimental science. Both as an approach to control and as providing basic background information on radiation exposure and effects on man, it is essential, the experts agreed, that methods be found of recording exposures to individuals and populations, however difficult this may prove.

Information Submitted by the World Health Organization to the United Nations Scientific Committee on the Effects of Atomic Radiation

In the "Conclusions of the First Session" of the United Nations Scientific Committee (A/AC.82R.10 of 27 March 1956) it was stated that "This year the human

geneticists will meet at a congress on human genetics. This opportunity should be used, with the assistance of the World Health Organization to seek advice about the possibility of setting up a standard of recognition for one or more clearly recognizable medical conditions thought to be largely or solely genetic in origin."

A statement describing the United Nations Scientific Committee's request was made at a plenary session of the International Congress of Human Genetics held at Copenhagen in August 1956. There was no formal response to this request from the Congress itself. However, a Study Group on the Effect of Radiation on Human Heredity had been arranged by WHO so as to follow immediately after the International Congress on Human Genetics, and the President and a number of the members of the Conference took part in this Study Group.

A reply to the request of the United ations Scientific Committee on the Effects of Atomic Radiation was formulated during the meetings of this Study Group and the reply is attached as document A. Since this reply is to a considerable extent supplemented by the report and working papers of the Study Group, these are also attached for the consideration of the Committee.

The Study Group convened by WHO on the Effect of Radiation on Human Heredity was designed to have three objectives:

1. To provide a small symposium of papers on the effects of radiation on human heredity.
2. To formulate in simple terms the desirable lines of further research on the effect of radiation on human heredity.
3. To give some recommendations in the particular province of WHO.

Document A

REPLY TO A QUESTION RAISED BY THE UNITED NATIONS SCIENTIFIC COMMITTEE ON THE EFFECTS OF ATOMIC RADIATION

There are at the present time no convenient indicators of recent genetic damage in man, and standards which can be applied in widely separate areas for recognition of hereditary characters are extremely difficult to establish even in the best laboratory conditions. Nevertheless, new methods of recognition are being developed. Techniques are available for accurate identification of serological traits (e. g. blood antigens) and other chemical specificities (e. g. haemoglobins, serum proteins, aminoacids in urine, factors controlling clotting of blood). Ophthalmological tests are also relatively exact but require co-operation of the patient. Many hereditary conditions can only be correctly diagnosed post mortem. Thus it would seem inadvisable to make definite recommendations for standardization on a considerable scale at the present time. If however the urgency of the problem necessitates an immediate attempt to select a group of "indicator traits" then, on the basis of experience to date, the following provisional list is suitable for setting up "standards of recognition":

Retinoblastoma
Neurofibromatosis
Aniridia
Acrocephalosyndactyly
Osteogenesis imperfecta
Chondrodystrophic dwarfs of all kinds
Haemophilia
Sex-linked infantile muscular dystrophy (Duchenne type).

It is emphasized that if "indicator traits" are used in the manner implied by the question, as many traits as possible should be used in the same area at the same time. At the same time variation in the sex ratio should be studied as an index of mutation.

In setting up "standards of recognition", human geneticists and appropriate specialist physicians should consult.

STUDY GROUP ON THE EFFECT OF RADIATION ON HUMAN HEREDITY

Copenhagen, 7–11 August 1956

Members:

Dr. T. C. Carter, Radiobiological Research Unit (Medical Research Council of Great Britain), Atomic Energy Research Establishment, Harwell, Berks, England

Dr. W. M. Court Brown, Group for Research into the General Effects of Radiation (Medical Research Council of Great Britain), Radiotherapy Department, Western General Hospital, Edinburgh, Scotland

Dr. S. Emerson, Biology Branch, Division of Biology and Medicine, US Atomic Energy Commission, Washington, D. C., USA

Dr. N. Freire-Maia, Laboratory of Genetics, University of Parana, Curitiba, Parana, Brazil

Dr. A. R. Gopal-Ayengar, Biology Division, Department of Atomic Energy, Indian Cancer Research Centre, Bombay, India

Dr. A. Hollaender, Biology Division, Oak Ridge National Laboratory, Oak Ridge, Tenn., USA (Chairman)

Mr. G. H. Josie, Research and Statistics Division, Department of National Health and Welfare, Ottawa, Canada

Dr. S. Kaae, Finseninstitutet og Radiumstationen, Copenhagen, Denmark

Professor T. Kemp, Universitetets Arvebiologiske Institut, Copenhagen, Denmark

Dr. J. Lejeune, Centre National de la Recherche scientifique, Paris, France

Professor H. J. Muller, Department of Zoology, University of Indiana, Bloomington, Ind., USA

Professor J. V. Neel, Heredity Clinic, Institute of Human Biology, University of Michigan, Ann Arbor, Mich., USA

Dr. H. B. Newcombe, Biology Branch, Atomic Energy of Canada Limited, Chalk River, Ont., Canada

Professor L. S. Penrose, The Galton Laboratory, University College, London, England

Professor R. M. Sievert, Institute of Radiophysics, Karolinska Hospital, Stockholm, Sweden

Dr. C. A. B. Smith, The Galton Laboratory, University College, London, England

Professor A. C. Stevenson, Department of Social and Preventive Medicine, The Queen's University of Belfast, Institute of Clinical Science, Belfast, Northern Ireland (Rapporteur)

Professor O. Freiherr von Verschuer, Institut für Humangenetik der Universität Münster, Münster, Germany

Dr. Bruce Wallace, Biological Laboratory, Long Island Biological Association, Cold Spring Harbor, Long Island, N. Y., USA

Professor M. Westergaard, Universitetets Genetiske Institut, Copenhagen, Denmark

Observers:

Dr. R. K. Appleyard, Acting Secretary, Scientific Committee on the Effects of Atomic Radiation, United Nations, New York, USA

Dr. R. A. Silow, Specialist in Atomic Energy, Agricultural Institutions and Services Branch, Agriculture Division, FAO, Rome, Italy

Dr R. L. Zwemer, Chief, Division of International Co-operation for Scientific Research, Department of Natural Sciences, UNESCO, Paris, France

Secretariat:

Dr. P. Dorolle, Deputy Director-General, WHO

Dr. M. Pizzi, Chief, Epidemiological Information and Morbidity Statistics Section, WHO

Dr. I. S. Eve, Medical Officer in charge of Questions dealing with Atomic Energy and Health, WHO

Two national committees reported in 1956 on the effects of ionizing radiation on man.[1] Although difficult to compare in detail, these reports come to remark-

[1] United States of America, National Academy of Sciences (1956) Biological effects of atomic radiation; Great Britain, Medical Research Council (1956) The hazards to man of nuclear and allied radiations, London.

ably similar conclusions as to the probable effects on the descendants of populations exposed to increased amounts of such radiations.

The emphasis in both these reports was, however, on trying to set some quantitative limits to the risks in the light of existing knowledge.

The purpose of assembling the Study Group whose report is presented here was essentially twofold. The first aim was to obtain the opinions also of authorities on genetics from countries, other than those whose national committees have already stated their views. The second was to have the opinions of a number of experts on an aspect relatively little considered in the national reports—namely, the lines of research which are needed in the light of present knowledge, to increase our understanding of the genetic effects of ionizing radiations on man.

The Group met, by courtesy of the Rector of the University of Copenhagen, in the Council Room of the University, from 7 to 11 August 1956. The agenda adopted was intended to permit exploration of the views of the members on the theoretical and practical difficulties in closing present gaps in knowledge. The procedure adopted was for a number of members to open discussions either by short statements or by submission of invited papers. The opportunity was also taken to discuss a number of subjects not formally introduced.

The papers submitted are reproduced as annexes to this report and whilst the report itself represents the combined opinions of all the members of the Study Group, the annexed papers give the individual views of the authors.

The proceedings were opened by Dr. P. Dorolle, Deputy Director-General of the World Health Organization, and the Group elected Dr. A. Hollaender as Chairman.

1. INTRODUCTION

Man's most unique and precious possession is his heredity material which must determine the health and orderly development of future generations. The Group is of the opinion that the well-being of descendants of the present generation is threatened by developments in the use of nuclear energy and of sources of radiation. Both of these developments are inevitable and they should contribute much to man's social and cultural development. It would seem therefore that some risk must be accepted, but if the dangers are to be minimized every possible step must be taken to reduce the exposure of man and to understand the effects of exposure. Only in the light of more knowledge can decisions be taken to define more accurately the maximum amount of exposure which may be accepted by individuals and populations without risk of serious harm.

Radiation has been demonstrated to be one of the agents which produces mutation in a wide range of organisms from bacteria to mammals. The Group is agreed that additional mutation produced in man will be harmful to individuals and to their descendants. While there may be inherent and environmental mechanisms which modify the impact of these mutations over periods of many generations, the effectiveness of such mechanisms in man is not known. In essence then, all man-made radiation must be regarded as harmful to man from the genetic point of view.

In recent years, considerable quantitative knowledge has been accumulated on the basic mechanisms of genetics. There are strong grounds for believing that most genetic effects are very closely additive so that a small amount of radiation received by each of a large number of individuals can do an appreciable amount of damage to the population as a whole. There are, however, many gaps in knowledge particularly concerning these effects in man. These gaps will only be closed after a great expansion of general and *ad hoc* research in genetics and other fields of biology.

The Group has received the following resolution passed by the First International Congress of Human Genetics in Copenhagen and it notes and agrees (while at the same time recognizing that WHO's work is only concerned with the peaceful use of atomic energy):

"The damage produced by ionizing radiation on the hereditary material is real and should be taken seriously into consideration in both the peaceful and military uses of nuclear energy as well as in all medical, commercial and industrial practices in which X-rays or other ionizing radiation is emitted. It is recommended that the investigation of the amount and type of damage and of related genetic questions, be greatly extended and intensified with a view to safe-guarding the well-being of future generations."

The Group agrees with the memorandum, entitled "Human and Medical Genetics", which was submitted in 1955 by the Government of Denmark to the World Health Organization.[3]

This Group takes note of the report of the National Academy of Sciences of the United States of America and that of the Medical Research Council of Great Britain. It is not intended to reproduce any of the material in these reports but the Group notes the substantial similarity of the findings and recommendations of these reports and is in essential agreement with them.

2. NATURAL AND MAN-MADE SOURCES OF IONIZING RADIATION

The present sources of ionizing radiations of interest for the treatment of problems related to the genetic effects in man include the following:

Natural sources

1. Cosmic radiation.
2. Naturally occurring amounts of radium, thorium and potassium in the earth crust.
3. Content of natural radioactive elements in living tissues.

Man-made sources

4. Radioactive material and technical arrangements producing ionizing radiation (such as X-ray tubes and other particle accelerators, nuclear reactors, etc.) used in education, science, medicine, industry and commerce.
5. Sources used by the population for other purposes than those mentioned in 4 (radioactive luminous compounds on watches and other articles for common use, television sets, etc.), although such sources are much less significant than those mentioned in 4 and 6. It is important, however, that their existence be recognized.
6. Artificial radioactive elements distributed by man in nature.

Information as to the contributions to the doses received by individuals and by large population groups from the various sources listed above is summarized in Professor R. M. Sievert's paper, from which it is obvious that as regards the average dose to the gonads the most important contributions are at present those from the natural radiation (normal level: between 2 and 5 r per individual in 30 years) and from the radiation received by patients undergoing medical X-ray examination (probable average between 1 and 3 r per individual in 30 years). If therapeutic exposures are also considered, the "total" exposure to a population might be greater. It is, however, difficult to get sound data for estimating how much exposure is received in therapeutic exposures to persons before the age at which procreation may be expected to be ended.

It may be noted that at the present time the highest dose to the gonads caused by natural radiation in areas with a large population seems to exist in parts of Travancore, India, on ground containing monazite sand (possibly of the order of between 10 and 20 r per individual in 30 years).

3. IMPORTANCE OF RECORDING RADIATION EXPOSURE IN INDIVIDUALS AND POPULATIONS

From a genetic point of view the total accumulated dose is the important one and for this reason the measurement of exposure to ionizing radiations is an essential preliminary to attempts to relate dosage received to effects in man. For such measurements to be useful, the information must be recorded systematically. Unless the information is available in the form of the dose received by individuals, records of exposure would be unsuitable for many purposes and therefore some system of registration is essential. The effect of recording would almost certainly be to cut down the exposures given in medical diagnosis and treatment, since it would impress radiologists and technicians with the magnitude of such exposures. In one hospital where such recording was started there has been a 30 per cent. reduction in the total exposure of the staff. Doubtless a similar system of recording in diagnostic practice would reduce the exposure to the patients. This in itself would be a sufficient justification for introducing the procedure. It seems likely that the two national reports will already have done much to overcome the hesitation to record the dose on the part of those who would be concerned in making such records but that a recommendation from this Group would also be helpful.

[3] Off. Rec. Wld. Hlth. Org., 68, 147.

The Group is conscious that the adoption of any system of recording dosage will give rise to difficulties because it will increase the burden of work of radiologists and their staffs. Nevertheless, it feels that the importance of these procedures is such, and is so well recognized by radiologists that both those in charge of radiological departments and other physicians who use X-rays will be co-operative.

Whatever system adopted should take into account three desirable requirements:

1. That the individual will not, through lack of information, accumulate excessive exposure.
2. That information becomes available as to how much exposure to the gonads is received at each age in individuals and on an average per head of population.
3. That it should be possible to recognize the amount of exposure received by the parents of a given child. (Eventually, the information would be available for several generations.) This information is particularly valuable for purposes of genetic analysis.

The Group suspects that exposures in some industries and in scientific work are unnecessarily high. Exposures from these sources should be recorded in such a way that the dosage received can be related in individuals and populations to that received from other sources.

It seems unlikely that all countries would favour or indeed would be able to introduce the same standards of registration. Although it is expected that recommendations on mechanisms of recording will shortly be available from the International Commission on Radiological Protection, there should not be any delay in improving the standard of recording of exposures.

Whatever procedures of recording and registration are adopted will entail a large expenditure of money and effort. The need, however, is urgent. Further, the present is the appropriate time to initiate such procedures, since the introduction of atomic energy for industrial use and the extension of the use of radiation tools in biology and medicine make it possible to start with such procedures at an early stage of a period of rapid development.

4. RESEARCH

General

Additions to the understanding of the effects of radiation in man come from a very wide field of research. It is impossible to forecast what work in biology or genetics will contribute information relative to the problems. Accordingly, the Group is strongly of the opinion not only that as much experimental work as possible should be done on radiation effects on suitable organisms and such controlled observation studies as offer in man, but that there should be an intensification of all human and experimental genetic research. The Group feels that there should be the closest possible collaboration between those working in the experimental and human fields: their work is complementary. Each should be stimulating the other's research projects. This need for intensification of research in man and in other organisms raises problems of finance and of shortages of trained research workers. Both these difficulties are likely to be intensified if new areas of work, such as that on tissue cultures, chemical mutagenesis, serology, biochemical genetics and epidemiological problems of genetic disease are to develop as rapidly as is desirable. The problem of manpower shortages, in regard to both biologists and physicians, tends to be perpetuated by lack of career opportunity for those working on genetics. There is also an insufficient number of institutions where an adequate training in genetics, particularly in human genetics, can be given.

It is possible that the results of much effort in these fields will prove disappointing. Nevertheless, research workers and those supporting their work must have the courage to face the possibilities of such disappointments and still go forward.

The developments of nuclear energy would never have been made unless enormous risks of failure had been accepted. These innovations have extremely important implications among which the possible effects on man's genetic composition are outstanding. If there is to be a climate of public opinion favourable to the development of nuclear energy the peoples must be assured that investigations essential for their future health and welfare and that of their children will be undertaken on an adequate scale. This will require recognition by governments that very substantial financial provision must be made for genetic and other biological investigations essential to an under-

standing of the effects of radiation on man. Biological research in the past has suffered severely from lack of funds.

Specific

The Group does not feel that it should attempt to recommend specific research projects. Nevertheless, it seems desirable to recognize the larger gaps in knowledge as they appear at the present time. Among the fields in which the need for further work is urgent, if the genetic hazards of the irradiation of human populations are to be understood, the following appear outstanding. It should be emphasized that the rapid developments in genetics and other sciences must determine that recommendations for lines of research should only be accepted as tentative and should be revised periodically.

(*a*) *Further study of spontaneous and artificially-induced mutation.*—There is need for further study of the number and kinds of mutations produced by various doses and types of irradiation applied at different stages of the life-cycle under a variety of conditions and utilizing different kinds of organisms. The relatively limited opportunities to study irradiated human beings and their offspring should be exploited to the fullest extent possible. The appreciation of radiation-produced mutations is intimately related to a similar extension of knowledge concerning mutations that appear to arise spontaneously or as the result of the action of chemicals and of physical agents other than ionizing radiation.

(*b*) *Mutational component in the somatic changes produced by radiation and other means.*—The role of changes in the hereditary material of somatic cells in the genesis of leukemia, in other forms of neoplasms, and in alterations in the life span, is at present a controversial field whch needs clarification. The effects of low doses of radiation, including those from radioisotopes, require special study. An important method of attack on this problem is opened by recent developments in tissue culture techniques.

(*c*) *Means of protection against mutagenic agents.*—The pioneer studies which indicate the possibility that the production of radiation-induced mutations can be modified by various means have important implications for man and require extension in many directions.

(*d*) *Development of new and improved techniques for the identification of mutants.*—Efforts directed at developing more exact methods for the recognition of mutant individuals, and the distinction between the latter and phenocopies, should be intensified. It is important to prosecute studies of the frequency of a wide range of types of mutations including those with extremely small effects, recognizable only through special statistical or breeding techniques.

(*e*) *Manner of gene action.*—The phenomena of dominance, synergism and other forms of gene interaction, the multiple effects of a single gene and the role of environmental factors in the determination of traits require a great deal of elucidation, since they are highly important in appraising the effects of radiations. They should be studied both in man and in other organisms. In this connexion the prospects raised by the rapid advances being made on human biochemical specificities are of particular interest.

(*f*) *Selective factors in populations, with particular reference to the special conditions in man.*—Very little is known concerning the detailed effects of natural selection on the frequency of specific genes, constellations of genes, or cytological alterations. Such information is basic to attempts to understand the genetic composition of present and past human communities and to predict future trends consequent upon changes in radiation levels, medical practices, and social and economic conditions. These gaps in knowledge can in part be filled by the collection of relevant demographic and experimental data.

(*g*) *Patterns of mating in human populations and their genetic implications.*—A standard type of information always required in understanding the genetic composition of human populations and the effect on it of various amounts of radiation is the recording and interpretation of data on the consequences of inbreeding, assortative mating, geographical and cultural isolation and random genetic fluctuations.

(*h*) *Twin studies in man.*—These are recognized as being helpful in understanding many problems of human heredity. Such studies have already been extensively used but could be advanced by standardized registration of twins in various countries. They give useful information concerning the relative importance of hereditary and environmental influences.

(*i*) *Determination of the frequency of diseases with a significant genetic component, with particular reference to their epidemiology.*—This is fundamental for investigations on the significance of mutation as a cause of disease in man.

In this connexion central registration of human inbreeding, hereditary disease and variation is of the utmost importance. It is also of importance to know the number of people who on account of hereditary lesions have to be treated in hospitals or institutions or given social aid.

(*j*) *Study of populations of special genetic interest.*—Important information is to be obtained from the study of relatively stable, primitive communities, long isolated by geography or culture. Studies of this type require for their execution teams of persons from a variety of disciplines, such as cultural anthropologists, physicians and geneticists. It should be emphasized that the understanding of the genetic structure of contemporary populations will be greatly aided through these studies, which should be maintained continuously over a considerable period of time. The opportunity for these studies diminishes with each passing year. Among special communities to be studied are those receiving unusually large amounts of radiation, those in which the degree of inbreeding has long been very high or low, and those in which special conditions of selection have prevailed. In some investigations radiation physicists would be essential members of the teams.

(*k*) *Genetic mapping of human chromosomes.*—This is a highly specialized field in which encouraging advances are now being made. Among the possibilities to be exploited is the use of these data to aid in the identification of independently occurring mutant genes and in the study of chromosome rearrangements.

(*l*) *Cytochemistry and human cytology.*—Direct cytological observations should be conducted both on normal individuals and on those with suspected chromosomal abnormalities. Material from the individuals themselves as well as mutant cells of tissue cultures may be used in such work. Basic information concerning the ultramicroscopic structure and chemical composition of the hereditary material, and the manner in which this is altered by irradiation and other mutagens, is essential and should include information on lower organisms as well as man. The new developments in biochemistry, the emerging immunobiochemical investigation of tissue proteins, bone marrow and other tissues, the metabolic investigationes which may elucidate both physical and mental pathology, the new developments in electronmicroscopy which advanced our knowledge of the structure of human sperm all indicate the devolpment of new tools for the study of human genetics.

(*m*) *Development of further statistical methods.*—New mathematical methods have continually to be developed to deal analytically with problems which arise as the result of researches in human and in experimental population genetics. This is particularly so in relation to observations on the genetic structure of and intensity of selection in populations with regard both to traits due to single gene and those due to multiple gene effects. Special techniques requiring electronic computers will also be required for analysing data on genetic linkage in man.

5. SOME CONCLUSIONS

(*a*) The Group is of the opinion that there are too few institutions or large university departments devoted to general genetics and even fewer concerned with human genetics. It recommends the establishment of such institutions and departments and suggests that there could be no one ideal pattern. One of the benefits of such institutions would be to accustom people of different scientific disciplines having implications for genetics to work together. Physicians, general biologists, geneticists, biochemists, cytologists, serologists and statisticians are examples of the find of workers who may be needed. When such institutions are concerned with human genetics their location should have regard to the adequacy of existing medical services, to the kind and size of human populations available for field studies and to the adequacy of background vital statistics and general demographic information of the population concerned. For many purposes a population of about two million is optimal particularly for intensive epidemiological investigations. Such institutions, in addition to their research functions, could eventually serve as centres of elementary and advanced training in genetics.

(*b*) Such research departments and institutions should contribute much to teaching in general and human genetics. Medical undergraduates should all receive training in genetics and the teaching should be co-ordinated with that in radiology and in the use of radioactive substances in medicine, so that the genetic hazards of diagnostic and therapeutic procedures are thoroughly understood. Medical men training as radiologists should have specific, more advanced instruction in genetics. Health physicists, radiological physicists and radio-

logical physicists and radiological technicians should also receive instruction in genetics as part of their technical training.

It seems essential that instruction in genetics should be given to all scientists, particularly those whose work is likely to involve the use of radiation and radioactive materials in research. The principles of human genetics could with advantage be conveyed to those training in the social sciences by means of formal instruction. Finally, the Group is of the opinion that public education in genetics should be more common and adequate than it is at present.

(*c*) In the future it will be necessary from the point of view of preventive medicine and genetic hygiene to register serious hereditary diseases and defects in various populations or countries in the same way as, for instance, epidemic diseases. For that purpose, genetic hygienic ascertainment or registration will be an indispensable and necessary step. The recording of hereditary diseases and defects in various countries and regions is to be highly recommended.

(*d*) In may countries there are very few biologists or physicians properly trained in genetics. This situation will only be solved by producing more career opportunities in genetics, but may be alleviated by granting fellowships or subsidizing training at approved institutions in countries which can offer training facilities. It is possible, also, that advice and technical assistance could be given in connexion with research projects in countries with insufficient rosources in trained manpower to carry them out.

(*e*) It might be possible for a United Nations Agency to assist on request in administration or supervision of studies of specific populations over a period of years or by strengthening a research team or by giving advice on organization.

(*f*) In the past, United Nations Agencies have done useful service in contributing to the collection and standardization of vital and health statistics. It is recommended that such agencies continue their efforts and stimulate the efforts of others in the collection and publication of specific data such as fertility, consanguineous marriages and parental ages, which are so essential as background information in many studies in human biology.

(*g*) The Group wishes to call attention to the evidence that damage to body tissues produced by radiation after relatively small doses is, at least in part, mediated through effects on genes and chromosomes. There is also some evidence that the life-span may be reduced in mammals even by relatively small doses. *Ad hoc* investigations are urgently needed.

(*h*) The Group is particularly impressed with the genetic hazards of man-made radiation from sources used in medicine, industry, commerce and experimental science, etc. Both as an approach to control and as providing basic background information for relating quantitatively radiation exposure and effects on man, it is essential that methods be found of recording exposures to individuals and populations, however difficult this may prove.

There is reason to believe that radiation exposure can be much reduced, therefore, those in charge of sources of ionizing radiations should always ensure that there is adequate justification for exposing individuals to doses however small. On account of the danger to offspring resulting from irradition of the gonads by X-rays, consideration should be given to determining what efficient means of shielding the gonads could be devised and brought into general use. In addition, in every exposure the X-ray beam ought as far as practicable to be directed so that a minimum of radiation reaches the gonads.

ANNEX 1

DAMAGE FROM POINT MUTATIONS IN RELATION TO RADIATION DOSE AND BIOLOGICAL CONDITIONS [1]

(Formerly entitled "The conception that mutations accumulate following repeated irradiation")

1. ACCUMULATION

One topic which I have been requested to discuss is that of the accumulation of point mutations following repeated irradiation. An accurately additive

[1] Submitted by Professor H. J. Muller, Department of Zoology, University of Indiana, Bloomington, Indiana, USA. (This paper is a considerably modified version of that presented at the Study Group on the Effect of Radiation on Human Heredity.)

accumulation in the germ cells throughout life has as its necessary and sufficient conditions (*a*) that the induced mutations are stable, i. e. not subject to repair, (*b*) that there is no important amount of intercellular selection to alter the relative frequencies of the mutant and non-mutant cells within a given individual during his lifetime, and (*c*) that radiation given at one time does not by some long-term aftereffect influence the mutagenicity of cells irradiate at a later period. These questions will be considered in turn.

(*a*) Changes of a point-mutational nature induced by radiation have not shown, as a class, unusual instability as compared with those arising spontaneously. Although the possibility is not excluded that there may be a relatively short period, of the order of one or a few cell cycles, before a mutation becomes fully completed and permanent (as in the work of D. Lewis, 1951, on *Oenothera*), this circumstance would not in ordinary cases affect the accumulation process.

(*b*) As for intercellular selection, except for the special case of drastic lethals arising in the X chromosome of a male, which have been shown in a series of experiments with Drosophila (by Kossikov, 1936, Shapiro, 1936, etc.) to be subject to selective elimination in spermatogonia, there is no reason to expect point mutations of the usual "recessive" sort, appearing heterozygously, to influence the multiplication or survival of immature germ cells appreciably. That mature germ cells are not thus influenced was shown long ago by Muller & Settles (1927). The most pertinent evidence on this point as regards immature germ cells, in an organism related to man, is given by experiments carried out by Russell (1951, 1956) in mice to test this very question. The failure of the mutation rate to decline in groups of offspring derived from spermatozoa ejaculated at increasing intervals after spermatogonial irradiation, shows both the absence of germinal selection against the mutant cells (point b) and the essential permanence of the mutant genes (point a).

(*c*) Direct tests of the accuracy of accumulation of lethals induced in Drosophila spermatozoa have been made by comparing their frequency at a given total dose after one treatment concentrated into a short time with that after a divided treatment of the same intensity and after a protracted treatment delivered at a low dose rate. It was found that the frequency depended on the total dose regardless of its distribution in time. When the diverse experiments of this kind carried out by different investigators (see review by Muller, 1954b, page 278, citing work of Patterson, Timoféeff-Ressovsky, Ray-Chaudhuri, Makhijani, Stern and others), are all taken into consideration together, it is found that the time-intensity relation was varied over a range of about 300,000 times, without any influence on the frequency of the mutations produced. Thus, a dose delivered in divided or protracted form over a month's time was as effective as one of the same total amount given in a few minutes. Tests have also been carried out, by Kerkis (1938), by Timoféeff-Ressovsky (1934), and recently by Oster (1955), that showed an additive relation when irradiation was given successively at two widely separated stages, to the immature and mature male germ cells respectively.

The reservation must be made that mutations not of the point variety, that is, those involving gross structural changes of chromosomes, which result from a combination of two or more independently produced chromosome breaks (Muller 1938, 1940) do, as expected, show an increase in frequency when the radiation is delivered in more concentrated form, provided union of the broken ends of the chromosomes can occur to an appreciable extent during the time of the longer treatment. This condition does not hold in mature spermatozoa, the type of cell used for most of the above-mentioned timing experiments, for union of broken ends cannot occur during this stage (Muller, 1940), but it does hold in other germ cells, in which therefore more lethals of the structural type result from concentrated than from very protracted or divided treatments (Herskowitz & Abrahamson, 1956). In the experiments cited in the preceding paragraph in which both immature and mature male germ cells were used there was no test of this matter, since the intervals between irradiations were long enough to avoid interactions between the effects of different exposures.

On the other hand, in gonial cells, which allow union of broken ends during treatment, relatively few of the mutations are of the "structural" type anyway. Moreover, low doses or dose-rates, such as those ordinarily encountered in human occupational exposures, produce relatively few structural changes as compared with point mutations even in the cells (spermatids and spermatozoa) most susceptible to their production, and produce still fewer in gonia. It must further be noted that at these low doses or dose-rates the rare structural changes which

do occur must in most cases have had both or all of their constituent breaks arising as effects of the same fast particle. The frequency of these changes would therefore, in such case, be independent of the time distribution of the irradiation. For these reasons, conditions would seldom be encountered, except in oöcytes, that resulted in overall frequencies of mutations (counting, together, both those of a point and of a grosser nature) differing perceptibly from those expected on an additive relation to the radiation dose. And when point mutations only were considered, the relation would be accurately additive.

2. LINEAR RELATION TO DOSE

Another expression of this additive relation, in the case of point mutations, is shown by the linear dependence of their frequency on radiation dose. That lethals induced in Drosophila spermatozoa do vary in frequency in this way has been abundantly shown for moderate and low doses, at which most of them are point mutations, in a great array of investigations, beginning with those of Hanson & Hayes (1929) and of Oliver (1930) and proceeding through many others to those of Uphoff & Stern (1949), which brought the dose down to 50 and 25 r. In experiments involving a lesser range of dose applied to spermatozoa of Drosophila, visible, non-lethal mutations, which include fewer structural changes than lethals, were found by Timoféeff-Ressovsky to show a linear relation to dose, and a linear relation for them was likewise found by the Indiana group when appreciable structural changes were excluded by cytological examination. Russell has also found a linear relation for visible mutations resulting from the irradiation of the spermatogonia of mice with moderate doses. A linear relation for visible mutations in higher plants was found by Stadler (1928) and in lower plants, for moderate doses, by Hollaender and others (see previously cited review).

It is true that in occasional experiments with very low doses results different from those expected on a strictly linear relation have been obtained. For instance, too few induced lethals seemed to be obtained by Caspari & Stern (1948) and too many induced visibles by Bonnier & Lüning (1949). However, these experiments were carried on at levels of dose so low that small sources of error had a relatively great effect. These sources of error include, in the case of visible mutations, differences in the degree of adverse selection against the mutants as between the control and treated series, caused for instance by differences in degree of crowding. In the case of both lethals and visibles, the numbers of mutations obtained at these doses are so low as to have a relatively large statistical variation. Moreover, the proportion of those obtained which were induced by the radiation is subject to a far higher error still, since it is represented by the difference between the frequency found at the low dose and that found in the control material. Inasmuch as at doses of 25 and 50 r the spontaneous (control) frequency may be a good deal higher than the induced frequency the error of this difference may be relatively enormous. This is especially true because the spontaneous frequency itself is subject to much more variation than that of random sampling. One source of such variation lies in the origination of mutations in clusters of common origin, caused by mutations in early germ cells. Another lies in the great differences between the spontaneous mutation rate existing in different lines, which may be as great as an order of magnitude and give evidence of being caused by genes (Muller, 1928), now called "mutator genes". Finally, both the spontaneous and the induced mutation rates vary considerably according to the history of the germ cells used (e. g. Muller, 1946, Lüning, 1952). Very special techniques are necessary for minimizing these various sources of error.

In view of these difficulties it is not surprising that experiments to test the linear relation have not yet been pushed below 25 r. However, genetic and other techniques have over the course of several years been worked out at Indiana which should now allow significant results to be obtained at doses as low as 10 or even 5 r. Work on the necessary scale would require the co-operation of a group working over some two years and examining several hundred thousand cultures, a project that we estimate might cost some $18,000. We are not especially desirous of carrying it out ourselves since even if the necessary support were provided the work should inevitably entail much digression from our other activities. We should therefore be glad to co-operate in furnishing the stocks and techniques and aiding in the supervision of the work if it were to be carried on elsewhere, although if no other suitable place could be found for the project we would not exclude the possibility of our conducting it.

The fact that the relation is linear, even at 50 r, and even when the irradiation of sperm cells is protracted for several weeks, makes it very probable already that the relation is linear all the way down to zero. For in some of this work it can be shown that there must have been hours between the traversing of a sperm cell by one ionization track and its traversing by another. If, however, the linear relation can be pushed down to doses as low as 5 r (or if at this dose the frequency can merely be shown to be more nearly proportional to the dose itself than to its 1.5 or .5 power), then we would have a justification for concluding with a very high degree of assurance that the relation was indeed linear all the way down to zero. This is because the ionizations are not produced separately but occur in the course of the tracks of the fast ionizing particles (the released electrons). Thus the ionizations come in spurts and a cell either gets a spurt or it does not. With very low doses, such as 5 r or less, an individual spermatozoon would hardly ever be traversed by more than one track, that is, it would not have received more than one spurt. Hence lowering the dose would not have the effect of lessening the number of ionizations in cells that received a spurt but only of lessening the number of cells that received any spurt at all. For these very low doses, then, the mutation frequency would be proportional only to the number of cells "hit," which is necessarily proportional to dose. Therefore we could justifiably extrapolate the results from 5 r linearly all the way down to zero. We need only make the one proviso here that the mutations produced in a cell by ionizing radiation result from ionizations or activations arising in that cell itself, not from those in the medium, but there is evidence from other work (see Muller 1954b) that this is true for mutations produced by ionizing radiation in Drosophila.

3. INFLUENCE OF LOCAL CONCENTRATION OF ACTIVATIONS

Even if we assumed the linear relation to hold all the way down to zero for X-rays and gamma-rays, this still would not mean that a given mutation necessarily results from just one ionization or excitation. For, many of the ionizations and excitations are grouped together in small clusters in the course of the tracks of the fast particles and it is possible that a cluster rather than a single quantum change is usually required to cause a gene mutation or chromosome break. At first sight it might be thought that this view is contradicted by the lack of influence of intensity changes on the dose-mutation rate relation, inasmuch as this result indicates that a given number of nearby ionizations when crowded together in time are no more mutagenic than when scattered in their time distribution. However, this inference is inapplicable to the question at issue, because the crowding attained in this way is much less than that within the minute clusters formed in the course of the track of a fast particle. That a cluster of such density is in fact more effective mutagenically than the same number of scattered activiations is shown by recent work (e. g. Ives, Mickey, Muller, all 1954) proving the higher effectiveness of neutrons than of X-rays in producing both point mutations and chromosome breaks. Other evidence to the same effect lies in the lower mutagenic effectivenes apparently shown by betatron radiation having an energy of about 15 Mev, as compared with ordinary Xrays, inasmuch as the radiation of higher energy is thought to result in a somewhat lesser amount of clustering than do ordinary X-rays (Herskowitz, Muller & Laughlin, 1956). I am inclined to view the greater effectiveness of more densely crowded activations in terms of the Watson-Crick model of chromosome structure, by supposing that a hit on both complementary strands at corresponding, or nearly corresponding, points is more likely to result in a permanent alteration in the chromosome than when just one of the strands is changed.

4. COMPLICATIONS AT HIGH DOSES

The breakage of chromosomes by radiation complicates in more than one way, at high doses, the relation between radiation dose and the observed frequency of visible or lethal mutations. For one thing, the ensuing chromosome abnormalities often kill the affected cells or their descendant cells by causing chromosome bridges at a subsequent mitosis, and, short of such an effect, can lower the multiplication rate of the descendant cells or even kill them by means of the resulting aneuploidy (the abnormal proportions existing between different chromosome parts). This circumstance would not in itself affect the observed frequency of point mutations were it not for the fact that germ cells in different

stages of the reproductive and mitotic cycles differ from one another in their susceptibility to having their chromosomes broken, and that they differ in a parallel manner in their susceptibility to having point mutations induced within them. At higher doses there is necessarily more killing off of the more susceptible cells, relatively to the less susceptible ones, by means of chromosome changes, than at lower doses (as well as more reduction of the multiplication rate of those not actually killed). Now, since the cells of the groups more injured in this way are also the ones that have had more point mutations produced in them it follows that at high doses there is more selective elimination (or reduction in relative numbers) of the germ cells containing point mutations as compared with the unmutated ones than there is at low doses. Hence, at higher and higher doses the frequency of point mutations observed among the offspring will fall further and further short (in a relative sense) of the frequency with which the point mutations had actually been produced, and the graph of the observed results will bend down ever further from the straight line extrapolated from the data obtained at low and moderate doses.

It is evident that the more heterogeneous in the susceptibilities is the lot of irradiated germ cells from which the given offspring are derived, the more pronounced will this falling off from linearity be. A very marked illustration of this effect, involving only a one-and-a-half-fold increase in observed lethal mutation frequency with a fourfold increase in dose (from 1000 to 4000 r) was obtained (Muller, Abrahamson, Herskowitz & Oster, 1954) by taking offspring from copulations of Drosophila males that had occurred seven to 10 days after their irradiation as just hatched imagos. The reason the effect was here so marked was because, as Lüning's already mentioned work had shown, the germ cells released during this period were at the time of irradiation in a number of different stages, having widely different susceptibilities. Although the irradiation of a quite homogeneous lot of germ cells would, theoretically, fail to give rise to any effect of this find, this has so far remained, in Drosophila, an ideal situation, that has probably not been obtained in practice.

Even gonial cells are of differing mutagenic susceptibilities, depending, for one thing, upon whether or not they happen to be in mitosis at irradiation. As Oster (1954) has shown, gonial cells containing the condensed chromosomes of mitotic stages (produced in this case by colchicine or acenaphthene treatment) are, like other cells with condensed chromosomes, more susceptible to radiation mutagenesis. This fits in with Russell's finding that the mutation frequencies found on examination of mice derived from irradiated spermatogonia, although linear for the dose range 300 r to 600 r, fell markedly below the expectation for linearity when a dose of 1000 r was used.

In organisms such as Drosophila and, probably, moulds, in which mutations of visible or lethal expression can arise in connexion with gross structural changes of chromosomes, either as position effects or as deficiencies, the complication exists that the frequency of these structural changes rises more rapidly than the dose (approximately as its 3/2 power, Muller, 1938, 1940). The observed mutants, unless analysed for gross structural changes, will represent a mixture of these and point mutations (the latter in turn consisting of gene mutations and minute structural changes, both of which vary linearly with the dose). Thus at lower doses, where the great majority of the mutations are in the point category, the frequency will be linearly related to dose, but at high doses, where the gross structural changes become numerically important, it might be expected that the overall frequency of lethal and of visible mutations would gradually rise, to approach the 3/2 power relation. Just this is seen in the results for visible mutations observed by Stapleton, Hollaender & Martin (1952) after irradiation of spores of the mould *Aspergillus*, whereas the offspring obtained after irradiation of mature Drosophila males have in most experiments seemed to show a linear relation for lethal and for visible mutations even at high doses. The interpretation of this at first sight paradoxical result is doubtless to be sought in the fact that in these experiments with Drosophila the germ cells used had been heterogeneous enough when irradiated to result in a tendency of the frequency to fall from linearity, in consequence of selectice elimination of the products of the more susceptible germ cells, and that this tendency largely compensated for the rise above linearity that would otherwise have been produced by the ever greater relative numbers of structural change mutants arising at the higher doses.

Because of these complications results with high doses are apt to be erratic and difficult of anlysis. Thus observations with moderate doses are better suited for arriving at an understanding of the fundamental frequency-dose relationship.

5. INFLUENCE OF CELL TYPE ON INDUCED MUTATION RATE

It has long been known (e. g. Stadler, 1928, Muller, 1930) that cells of different types or tages differ considerably in their susceptibility to mutagenesis by ionizing radiation. Although gross structural changes of chromosomes show the most variation in frequency with cell type, point mutations (including what are probably changes within a gene as well as minute deficiencies and rearrangements of one to a few genes) probably have a frequency range of at least fourfold when a given dose is applied to different types of germ cells. This is to be concluded both from results on lethals arising at moderate doses (at which relatively few of the changes are in gross chromosolne structure) and from visible mutations found by cytological observation to be free of discernible changes in the chromosomes.

Putting togther the results of earlier and later studies (see review previously cited and also recent papers by Bonnier & Lüning, 1953, Telfer, 1954, Abrahamson, 1956, and Oster, 1956), the early germ cells and gonia have the lowest frequency of induced point mutations yet the highest ratio of point mutations to changes of any kind that can be demonstrated to be structural (i. e. in these cells the structural changes fall to a minimum which is relatively much lower still). At these stages, the mutation frequency and distribution of types is much the same in male and female. In the later male germ cells, the overall mutation frequency, including that of recessive lethals, rises to a sharp maximum during the period of spermatid formation and transformation (although we must omit the preceding meiotic stages from consideration here as not being well enough known in this respect). Lüning has given reasons for inferring that much or all of the exceptionally high frequency of recessive lethals induced in the spermatid period involves those connected with gross and minute structural changes of chromosomes rather than true gene mutations. The overall mutation frequency, including that of recessive lethals, then falls sharply from the spermatid period to a second minimum to the immature spermatozoa (a minimum not nearly as low, however, as the preceding one in the gonia), only to rise again within the next few days until the time of ejaculation. After insemination, within the reproductive tract of the female, the male germ cells attain and maintain at a relatively constant level their highest known frequency of recessive lethals as well as of demonstrable structural changes, except for that found in the spermatids.

In rodents, the fact has long been known that ionizing radiation has a far more damaging effect on the genetic material when applied to mature or nearly mature male germ cells than when applied to immature ones (gonia), as judged by the killing of the resulting embryos. It remained for Snell (1935) to provide evidence that these effects, and the inherited "semi-sterility" which he found also to be induced in mice, were caused by gross structural changes of chromosomes, a class of effects with which we are not primarily concerned in this paper. Later, however, evidence was obtained by P. Hertwig (1941) that at those same stages there is also a relatively high frequency of production of point mutations by ionizing radiation, just as was known to be true in Drosophila. Fortunately, in man, the period during which the germ cells of the male remain in the gonial stage exceeds by over a hundred times that of the spermatid and spermatozoon stages, so that the high susceptibility of the latter stages presents a relatively minor practical problem. Thus it is the less mutable gonia of mammals, studied mainly by Russell, which are of greater interest in assessing the genetic damage produced by radiation in human populations. As noted in section 3, however, gonia themselves do not constitute one homogeneous class so far as susceptibility to mutagenesis is concerned, but may differ considerably, according to their developmental and mitotic stage and perhaps also their physiological condition.

As for the female germ cells, the point mutation frequency in the late oöcytes of Drosophila, during the last three or four days before ovulation, attains a level almost as high as that in the nearly mature unejaculated spermatozoa, when high doses of radiation are used (Muller, H. J., Valencia, R. M. & Valencia, J. I., 1950). However, in the previously mentioned work of Herskowitz & Abrahamson it was found that lethals induced at this stage show dependence on a higher power of the dose than 1, and on the timing of the dose, as well as other peculiarities, all indicating that a high proportion of them consists of small structural changes involving two independently produced chromosome breaks. These mutations (like many of those induced in spermatids and spermatozoa),

although not strictly point mutations, must usually be classed with them operationally since the making of the distinction is commonly impracticable or even impossible.

In mammals the germ cells of females may, according to one view, remain for a long time in a stage corresponding to the late oöcytes of Drosophila. It will therefore be important to determine to what extent mamalian female germ cells follow similar principles to those of Drosophila late oöcytes in regard to induced mutations. If they are long in such a stage, we should have to admit a notable departure from linearity for female germ cells. Whatever the answer may be, however, it is to be expected that for low doses, as for most occupational and diagnostic exposures, the frequency would be linearly proportional to dose even in late oöcytes (because of any given mutagenically sensitive region being so seldom traversed by more than one track), and that the frequency for a given low dose would not be lower in them than in gonia.

That somatic cells, like germ cells, can have point mutations induced in them by ionizing radiation was first shown by Patterson (1928), using Drosophila embryos and larvae. Calculations which I made on the basis of the early results, confirmed by studies by Timoféeff-Ressovsky (1929), and more recently by Lefevre (1950), show that for given genes the frequency of point mutations is similar to that obtained for gonia, or perhaps somewhat higher. This point is of importance in considerations of those effects of radiation on the exposed individual himself, such as leukaemia and other malignancies, which might have their basis in point mutations of his somatic cells.

With the development by Puck and his co-workers of methods of culturing and subculturing human somatic cells like micro-organisms, finding and breeding lines of mutant cells (1956b), and determining the effects of different doses of ionizing radiation (1956a), the way has now been paved for carrying forward to man the exact study of the induction of point mutations and other genetic changes in somatic cells. As an early result from this study, some evidence has already been adduced (Puck et al., 1956a) that the killing effect of the radiation on the cells is, as was to have been expected, caused by chromosome structural change rather than point mutation. It is probable on a number of grounds that this genetic killing of individual cells and genetic impairment of others, caused by gross chromosome changes, lies at the basis of much of the damaging effect of radiation on the body of the exposed individual, such as epilation, leucocytopenia, destruction of the intestinal lining and other manifestations of radiation sickness, production of cataracts, retardation and distortion of growth, reduction of regenerative capacity, and (probably the most important effect) reduction of the life span (see discussions by Muller, 1950b, 1956b, Quastler, 1956, Sacher, 1956).

6. ESTIMATION OF TOTAL DAMAGE FROM POINT MUTATIONS

The prime questions regarding the damage done to posterity by a given amount of radiation are, what will the total amount of that damage be, and how will it be distributed? In our previous treatment we have discussed how the frequency of lethal or visible mutations varies with dose and with type of cell, but we have not considered the absolute frequency of such mutations for any given dose, still less the total frequency of mutations of all kinds. It is this total frequency that counts. For, as long ago shown by Haldane (1937) and as later developed by Muller (1950a), in a population at mutational equilibrium (i. e. a population in which about as many mutant genes are dying out in each generation through death or failure to reproduce of the individuals containing them as are arising anew through mutation) the average reduction in fitness of an individual lies between the total frequency of all detrimental mutations, counting equally those with large and those with small effects, and twice that frequency. If all the mutant genes were strictly recessive the lower figure (the mutation rate, μ, itself) would apply, whereas if they were all dominant enough to be eliminated as heterozygates the figure would be wice this (2μ). As Muller (*ibid.*) pointed out there is good reason for inferring the higher figure, 2μ, to be nearly correct both in Drosophila and in man. This same figure for reduction of fitness would on the whole express the proportion of individuals in the population who would have to suffer "genetic death" (selective elimination by dying before maturity or failure to reproduce) to maintain the genetic equilibrium. Some reduction of the figure for elimination rate (probably by not more than a factor of 2) might, however, have to be made to allow for some synergistic operation by

detrimental genes: a mode of action giving individuals with multiple defects a lower survival rate than the product of the survival rates of those with the separate defects.

In estimating this total mutation rate for practical purposes only point mutations need usually be considered, since the great majority both of spontaneous mutations and of those that would be likely to be produced by radiation in a human population are of this nature. The first approach toward determining the total mutation rate in any organism was made independently and simultaneously in 1934–35 by Kerkis working in collaboration with myself and by Timoféeff-Ressovsky (see his and my review papers already referred to), using descendants of irradiated Drosophila males. Special techniques were used for the detection of mutations having neither a visible nor fully lethal effect, but only reducing the expectation of survival to maturity: the so-called detrimental mutations. Both pieces of work agreed that these mutations arise some three to four times as frequently as the fully lethal mutations. Essentially similar results have recently been reported by Käfer (1952), working under the guidance of Hadorn, and Falk (1955), working under the guidance of Bonnier.

It is admitted by all these investigators, however, that there had been little chance, by their techniques, of detecting mutations that reduced survival up to maturity by less than some 5–10 per cent. Moreover, there must be many mutations, undetectable by these techniques, the detrimental effect of which occurs mainly after maturity is reached or which affect reproductive capacity rather than individual survival. Thus the estimate that in Drosophila there are some five times as many harmful mutations altogether as the number of lethals, and some 30 times the number of sex-linked lethals, is a bare minimum, possibly only half the true value. It now becomes of great importance to extend the range of detected mutations to those with still less effect, and with other types of effect, so as to throw light on the extent to which the present estimate should be raised. As in the case of the proposed investigation of low dosage, we have for some years been developing techniques for such an attack in Drosophila, but again the work would necessarily be on so large a scale that group work and considerable expenditure (comparable in magnitude with that for the low dosage project) would be required.

In absolute numbers the above estimate becomes for a dose of, say 100 r applied to spermatozoa of young Drosophila males a day or two before their mating, or applied to late oöcytes, about one induced mutation in every 12 germ cells or one in six offspring. Thus a continuation of this exposure, applied to both sexes through many successive generations, would reduce the average fitness of the individual in the equilibrium population by about a sixth (some 17 per cent.) and would cause nearly one individual in six to meet "genetic death" in consequence of the irradiation. It can further be estimated (see below) that the total effect of spontaneous mutations in Drosophila is about half as much as this; that is, the given amount of radiation, applied at the stages specified, would constitute about twice the "doubling dose". But it should be borne in mind that these present estimates are in both cases minimal ones.

7. MANNER OF DISTRIBUTION AND EXPRESSION OF THE TOTAL DAMAGE

How does this mutational damage become distributed and expressed among the descendants? The amount of damage done by any given mutant gene in a heterozygous descendant may be represented as the amount of detrimental effect it would exert when homozygous multiplied by its amount of dominance (the ratio of its effect when heterozygous to that when homozygous). Now the dominance of lethals in Drosphila has been found both in work of Stern and his co-workers (see Stern et al., 1952) and of the present author and Campbell (see Morton, Crow & Muller, 1956) to average about 0.04 to 0.05, so that even these mutant genes with extreme effects would individually reduce viability in the heterozygote by only some 5 per cent. The merely detrimental genes are suspected on theoretical grounds (Muller, 1950a) to have somewhat more dominance than the lethals, and there has recently been some direct evidence for this (Falk, 1955), but even when considerable allowance is made for this possibility the effect exerted in a heterozygote by a detrimental is expected, on the average, to be less, absolutely, than that exerted by a lethal. Thus, taking individual mutant genes of all degrees, they should average well below five per cent. in individually lowering the fitness of the heterozygote. Since at the same time the visible effects of these genes in the heterozygote, *taken individually*, usually

escape notice, it follows that the effects of mutations induced by radiation in any one generation at a frequency comparable with that above considered would not ordinarily be observed among the next or any subsequent generation. Nevertheless the total loss of fitness in the next generation, being about one in six (the minimum frequency of offspring with newly induced mutations) times, say, one per cent. (to take a bare minimum for their average expression in heterozygotes) would in a population of 1 000 000 entail the "genetic death" of at least 1700 individuals of that generation. Moreover, a comparable amount of damage would continue to be exerted for scores of generations.

The number of generations that a mutant gene persists before causing genetic death is on the average about the reciprocal of the amount of damage it does to the heterozygote, so that the average Drosophila lethal in an autosome might be expected to persist for some 22 generations. However, the average persistence of a group of mutant genes is the *harmonic*, not the arithmetic, mean of the persistence of the individual mutant genes, and this value for the Drosophila lethals investigated turns out to be about 50 generations, though with a high error (see Morton, Crow & Muller, 1956). The persistence of detrimentals must be even greater. This is the so-called accumulation figure representing not only the average persistence of the mutant genes arising in a given generation but also the average amount of overlapping, within the individuals of any given generation, of mutant genes that arose in different generations, provided that the same mutation rate has existed in successive generations for a long period and mutational equilibrium has therefore been established. Hence if the 100 r exposure above postulated has been applied to Drosophila for many generations it is to be expected that each generation would be damaged at least 50 times as much as above calculated for the first generation of offspring (in fact, by an amount equal to 2μ or in this case 17 per cent.) Moreover, instead of one individual in six carrying a mutant gene induced by the radiation each individual would contain at least 50 X 1/6, or at least eight of them, on the average. Thus, although the effects of the mutant genes would seldom be individually noticed their collective effect would in the great majority of individuals be quite appreciable. It would of course tend to give a different pattern of impairment from one individual to another.

8. THE INDUCED IN RELATION TO THE SPONTANEOUS MUTATIONAL DAMAGE

The damage caused by the induced mutations is of course intermingled with that caused by spontaneous mutations. Although the amount of the radiation-induced mutational damage is largely independent of that caused by the spontaneous mutations it is helpful, in grasping its meaning, to compare it with that of the naturally existing mutational impairment since a species is in a sense adjusted to the latter and since, in man, we have a rough pragmatic familiarity with it. For this purpose it is desirable to be able to express spontaneous mutations in the same terms as those used above for induced mutations, namely, in terms of total mutation rate and loss of fitness. This is easily done, once estimates of these total values have been made for the *induced* mutations occurring at some given dose, provided only that the frequency of some particular group of mutations, e. g. sex-linked lethals, or visibles of a given collection or category (but preferably not those confined to just one allele series) has been determined under comparable circumstances both in unirradiated and in irradiated material. For there is good reason to believe that, for point mutations, the following relation will approximately hold: spontaneous total mutations/spontaneous mutations of given category-induced total mutations/induced mutations of same category. Thus, if figures are obtainable for the last three terms, the first one (the spontaneous total) can be solved for. The particular category best determined and most used for this purpose in Drosophila work has been that of sex-linked lethals.

Any *one* particular allele series (or "locus") cannot be relied upon by itself for the above purpose because the frequencies of mutation to different series may not bear the same relation to one another for spontaneous as for radiation-induced or otherwise induced mutations (see e. g. Giles, 1952). However, there is no reason to suspect that any broad phenotypic category or section of chromatin, or a whole group of allele-series chosen for their technical convenience, will show any consistent preference as between spontaneous and radiation-induced mutability. Experimental evidence that there is no such differential susceptability in Drosophila was obtained in the observation, by Timoféeff-Ressovsky (1937),

myself (see Patterson & Muller, 1930), and others, of the similar ratio of sex-linked lethals to sex-linked visibles both in unirradiated and irradiated material (especially when allowance is made for the relatively higher frequency of deficiencies and other structural changes after irradiation).

As noted above, the ratio of "total" mutations to sex-linked lethals in Drosophila when radiation is used has been estimated to be at least 30, and we may therefore (in accordance with the preceding formula) multiply the spontaneous sex-linked lethal frequency by 30 to obtain the spontaneous total. The problem arises, however, of what observed value of the spontaneous sex-linked lethal frequency to choose. For this value has been found to vary by at least an order of magnitude from one experiment to another according to the stocks used (Muller, 1928, confirmed by later workers) and to vary by more than half an order of magnitude according to the developmental history of the germ cells (Muller, 1946 and unpublished), not to speak of variations caused by temperature and other environmental differences within the natural range. However, the upshot of a large number of studies of the spontaneous sex-linked frequency in Drosophila, by different investigators, has shown that the great majority of individuals bred at 25° C. under reasonably favourable conditions, in such manner that the germ cells used to produce the offspring do not give undue representation to those with extreme developmental histories, have a sex-linked lethal frequency averaging about 0.1 to 0.2 per cent. This is true in both sexes, but the female value appears to vary less with germ cell history and commonly to approximate 0.17 per cent. whereas the male value, which is higher (0.2 per cent.) for the sperm released very early, is a good deal lower (e. g. 0.06 per cent.) for those released in what might be called the prime of life. Taking 0.14 per cent. as a reasonable average and multiplying it by 30, our minimum figure for the total spontaneous mutation rate per gamete is 4.2 per cent. and that for the zygote is 8.4 per cent., a figure which also represents the average reduction in fitness or risk of genetic death as a result of spontaneous mutations. It was on the basis of this estimate that an irradiation of 100 r given to Drosophila in the manner specified in section 6 was there stated to constitute about twice the doubling dose, inasmuch as it had been calcuated to give an induced rate of 17 per cent. per zygote.

From the above it will be seen that, in Drosophila at least, there is much more uncertainty about the amount of spontaneous mutational damage, because of the high variability of the spontaneous mutation rate, than about that caused by any given amont of radiation applied to a known stage or group of stages. Because of this uncertainty, determinations of the spontaneous mutation rate of any particular category of mutants in Drosophila, such as a given group of "visibles", should always, in order to have significance in relation to other work, be accompanied by a yardstick indicating the general mutability characteristic of the material studied. At present the most convenient such yardstick is to be found in the sex-linked lethal rate, which must be ascertained under precisely the same conditions. Only when such a yardstick is provided can we, for example, use data on the frequency of spontaneous mutations of given types to estimate the ratio they bear to the total mutation frequency, or to the frequency of some other particular category, inasmuch as these other quantities themselves are properly expressed in relation to a corresponding yardstick.

It is true that the radiation-induced rate also varies to some extent according to the stocks used (see below), the environmental conditions, and the germ cell stages involved. These differences, however, are not of a type which would usually throw our reckoning off nearly so much as in the case of spontaneous mutations since there is more knowledge of how they may be allowed for. But they must be taken into account.

9. SPECIES DIFFERENCES AND THE PROBLEM OF EXTRAPOLATION

In view of the evidence already referred to of the variation of the radiation-induced frequency of point mutations in Drosophila according to the type of cell irradiated, and the abundant evidence that has been obtained in recent years of the influence of conditions associated with the irradiation, such as oxygen concentration, enzyme-inhibitors, etc., on the frequency (see author's review, 1954b), it would be strange if genetic differences failed to affect the result. Indeed, Dubovsky (1935) reported that some stocks of *D. melanogaster* from widely separated localities differed by a factor of about 2 in the frequency of lethals produced by irradiation of the male. It is true that such differences can

be produced in the same stock by slight differences in the timing of the germ cells used, a matter not then realized, and that stocks may also differ genetically in their natural timing, yet genetic differences of many kinds would be expected to be capable of influencing the result. In the light of these considerations, however, it is rather noteworthy that, contrariwise, even the specific difference between *D. simulans* and *melanogaster* was found by Kóssikov (1935) not to be associated with a significant difference between the induced frequencies of lethals of flies of these two kinds. This similarity may indicate that the induced frequency, like the spontaneous one (see below), even though readily altered, tends to be maintained at a certain level by some active selective processes operating on features that, perhaps as a by-product, tend to maintain susceptibility to these mutagenic factors at the level found.

However that may be, it is not to be expected that widely different species, such as those of different phyla, would have similar induced or spontaneous mutation frequencies, either total or of any given overall phenotypic class and/or chromosomal type (such as sterility mutations or sex-linked lethals), nor that they would have a similar ratio of total mutation rate to that in such a category. One reason for this disparity is that the amount and distribution of the genetic material must differ enormously as between such organisms; another is that the processes whereby the genes reach expression must be so different that a superficial resemblance in effect would provide little or no indication of a homologous genetic basis. Thus even if the frequency of production of, for example, sex-linked lethals were known in a mammal, one certainly would not be justified in applying to this figure the Drosophila factor of 30 times, to estimate the total frequency of induced mutations in the mammal.

The case is, however, different when we use as our index of relative mutation rates in two widely different species a category consisting of the average frequency of origination, in each species, of members of a single allele (or pseudo-allele) series, often called the "specific-locus rate", provided that this average has been determined through observations of a number of different series ("loci") in each species and that most of the values found for the different series of the same species show (as they have done) a tendency to be clustered within about one order of magnitude. The reasonable agreement between the results for some 12 different allele-series involving visible point mutations (including those that are at the same time lethal) after irradiation of spermatozoa of Drosophila Muller, 1954a and unpublished) and also for some seven series after irradiation of spermatogonia of mice (Russell, 1952, 1956, Kimball, 1956), justifies us in speaking of an average or modal induced mutability for such an allele-series in each species. We may then infer that differences in the detectability of the mutations of the different series, in the complexity of the genetic regions concerned, and in their actual mutability, are usually insufficient to cause inordinate discrepancies between the values for the different series.

In Drosophila the ratio between the "total" and the average single allele-series rate is at least 10 000 (e. g. Muller, 1955b) and is probably a good deal higher. This value has been obtained by multiplying the ratio of "all" detrimentals and lethals to sex-linked lethals by the ratio of the latter to the average single allele-series frequency. (These two constituent ratios have of course been obtained in different experiments, under different conditions.) Are we now justified in assuming that a mammal would have at least as high a ratio as a fly of the "total" to the average single allele-series rate, and may we therefore multiply the latter rate, as determined in Russell's irradiation experiments, by 10 000, to obtain the minimum value for the total induced mutation rate in mice?

The justification for this procedure lies almost entirely in general considerations. The main consideration is that a mammal, by no matter what criterion, stands at least as high in the scale of biological organization as a fly, and probably a good deal higher as judged by its complexity of gross and histological structure, physiology, and behaviour. It would therefore be surprising if the genetic basis of the mammal were not as least as complicated and, accordingly, compounded of as many parts (such as nucleotides) as that of the fly. This would imply also that it had at least as many, and probably more, different ways of mutating, and that any one allele-series, on the average, represented no larger, but probably a smaller, fraction of all the mutational potentialities in the case of the mammal than in the case of the fly. The several times greater DNA content of the mammalian than of the Drosophila chromosome-set tends to support this inference.

It is to be noted that this method of obtaining a minimum estimate of the total induced rate in the mouse avoids any assumptions regarding the means of defining the limits of a gene or locus, and the number of such entities. It is true that in the past the argument has usually been stated in terms of genes or loci (but see Muller, 1955, 1956a, 1957) but this has, for the present writer at least, been only a short-cut mode of expression. For, what was meant by the "specific locus" frequency was really the frequency with which mutations arose that were on operational grounds to be classed as being probably members of the same allele series, without assumptions being made as to what proportion of mutations actually occurring in the chromosome region in question would fall into the given allele category. Moreover, although 10 000 was sometimes stated to be a minimum value of the number of genes or loci, as estimated by several very different methods, the justification for using it also as the ratio of total mutations to mutations in one average allele series ("specific locus") was that, empirically, the experiments on detrimental mutations, lethals, and allele-series mutations had shown this ratio to hold, no matter what the number of genes may be, or how we define them. It is quite possible, for instance, that some of the same chromosome regions that gave rise by mutation to members of a given visible allele series also gave rise to lethals and/or detrimentals (which may or may not have been included in the count of the allele-series frequency, according to whether or not they also produced the visible effect that served as the criterion), but this was irrelevant to the determination of the ratio since all the lethals and detrimentals of sufficient detectability to be recorded as such were included in the measurement of the frequency of these classes and therefore in the "total" rate. Thus the only relevant questions concerning the validity of the extrapolation process for obtaining a minimum estimate are whether or not a sufficiently representative sample of allele series has been obtained, and whether we are willing to admit the probability of the proposition that the average allele series, as operationally defined, would constitute at least as small a fraction of the total mutation rate in a mammal as in a fly.

If we grant these points and apply our factor of 10 000 to Russell's observed allele-series rate of 25×10^{-8} mutations per r in the spermatogonia of mice, we find as our minimum estimate of the total induced frequency in this material 25×10^{-4}, which may also be expressed by saying that there is at least one mutation per germ cell for every 400 r. As for the human induced mutation rate, we can at present only say that this is what it would be if it were like that of mice, that there are no data from man as yet that are inconsistent with this, and that this rate is about an order of magnitude higher than the induced rate in Drosophila.

On the other hand, we do have for man, as well as for the mouse, some data that allow us to estimate the spontaneous mutation frequency for allele series. As this matter has recently been discussed elsewhere (Mueller, 1957), an appraisal of the validity of this evidence will not be attempted here, except to point out, first, that the determination for man has the advantage of being based on large-scale data that give, as it were, a cross section of results from different genetic lines and from different ages and conditions of reproduction, and, second, that the results of the different allele series agree reasonably well with each other and, what is more surprising, that their consensus agrees well with the average based on mice.

Here again, then, is evidence of the operation of selective processes that tend to stabilize the mutation rate, as was noted in section 8 in connexion with the radiation-induced rate. Even more striking evidence of this, in the case of spontaneous mutation is the unexpected similarity between both these human and mouse values for the spontaneous allele-series rate and that (in the neighbourhood of 0.5×10^{-5}) deduced to be characteristic of Drosphila. It is true that thus far there has only been one series of experiments (Muller, H. J., Valencia J. I. & Valencia, R. M. 1950) in which a considerable group of spontaneous allele-series rates in Drosophila has been directly determined and in which at the same time a yardstick (sex-linked lethals) was used so that the obtained rates could be converted (as proved necessary) into more typical ones. However, approximately the same figure had been reached earlier by taking the typical spontaneous sex-linked lethal rate and dividing it by the ratio found to hold between the induced sex-linked lethal rate and the induced allele-series rate. Moreover, confirmation of the order of magnitude of this value (although probably involving some reduction of the value itself) is now being obtained in another series of direct observations, checked by lethals, conducted by Schalet at the Indiana

Laboratory. In any case, such a correspondence between such different species tends to impart confidence in the estimated orders of magnitude.

When, now, the factor of 10 000 is applied to the estimated value for an allele series in man, taking for the latter the rather conservative figure of 10^{-5}, we find that the minimum estimate of the "total" spontaneous mutation rate turns out to be 0.1 per gamete or 0.2 per individual, a value higher than has commonly been suspected to apply to our own species.

10. LIGHT FROM ANOTHER SOURCE

Extrapolation of the type above discussed is not the only means of arriving at estimates of the spontaneous mutation rate in man on the basis of existing data. As explained by Morton, Crow and Muller in a parallel paper (1956, see also Crow, 1956 and Muller, 1957) several different studies of the mortality found among the offspring of consanguineous as compared with non-consanguineous matings in man agree reasonably well in giving evidence from which it can be deduced that the average human gamete carries a mutational load accumulated from past generations which if it became homozygous would be twice as much as needed to kill the individual containing it at some time between a late foetal and early adult stage. Much of this load is probably scattered among diverse mutant genes any one of which would, if homozygous, entail a relatively small risk of death. There must in addition be a considerable load of detrimental genes in the gamete that tend to cause death before or after the period studied, or that interfere with reproduction rather than survival. Moreover, in a population living under more primitive conditions than those studied, more genes would find such expression than did so in the given populations. Finally, the individual himself carries twice as many such genes as the zygote. All in all, then, the load carried, mainly heterozygously, by the zygote is probably (if expressed in terms of the damage it would do homozygously) as much as about eight "lethal equivalents."

Now this rather directly measured load does not in itself tell us anything of the mutation rate per generation. However, if there are means of obtaining a reasonable estimate, by extrapolation or otherwise, of the relative amount of expression which this load actually attains in the average individual (a matter dependent upon the degree of dominance of the mutant genes and of the frequency with which occasional homozygosity occurs), we should then have a value for the average reduction of fitness. As noted previously, this would be almost equal to μ (the total spontaneous mutation rate) if the eliminations in the given population are brought about mainly through the homozygous effects and almost 2μ if the dominance is enough for elimination usually to be caused by the heterozygous effects. Now although the data from man are insufficient to allow us to set a value for the average dominance of mutant genes there are considerations (pointed out in some of the above papers) that allow us to set some fairly reasonable limits to such a value. Moreover, the value found for Drosophila lethals lies well between these limits. It is also possible to arrive at reasonable limits for the frequency of homozygosity caused by inbreeding. If then we extrapolate by taking the value for dominance found in Drosophila, and at the same time use in our reckoning the human inbreeding factor, we reach a value for reduction of fitness of approximately 0.1 per gamete or 0.2 per individual. This in turn gives us, as the value for the "total" spontaneous mutation rate, μ=0.1 per gamete, as was estimated by the other method, explained in section 9.

It must be pointed out that the present method involves data and methods of calculation both of which are entirely separate, as well as different in character, from those used in the other mode of attack. Although extrapolation is employed at one point in the present attack—namely, for estimating the degree of dominance—this item did not enter at all into the earlier calculation. Moreover, there seems little doubt, in consideration of observations concerned with man himself (see e. g. Levit, 1935), that the dominance factor in man would at least be within the same order of magnitude as that here assumed on the basis of extrapolation. If this is true, then the estimate for mutation rate here arrived at is likewise of the right order of magnitude, at least as a minimum value. A further circumstance to be taken into consideration in evaluation of the present result is that it was not realized until the calculations were carried through that they would give a value even distantly in agreement with what had been obtained by the other method, and that no attempt was made to manipu-

late them to obtain a satisfactory fit to expectation. For these reasons, it would seem that the present result, although itself involving interpolation, lends material support, from an independent direction, to that arrived at previously.

Although the present mode of attack is concerned only with spontaneous mutations, the estimate of the total spontaneous rate, as well as of the total load, thereby arrived at, affords an important independent possibility for gauging the total mutational damage which would be produced in a human population by radiation. Before this could be accomplished, however, there would have to be some means of determining, for some limited genetic category capable of being used as an index, the relation between the spontaneous rate and the rate induced by a given dose of radiation. Possibly somatic or tissue-culture mutations, if there were good reason to infer them to be of the point type, would be useful to provide such an index. At any rate, if it were once furnished, it would then be relatively easy to combine this information with that on the total load, derived from the results of inbreeding, so as to obtain a realistic view of the all-around and long-term meaning of a given dose of radiation.

Of course we are far from the final or exact answers concerning the total frequency of either induced or spontaneous mutations, or concerning the persistence factor, for any lower organism, and much further yet from these answers for man. But the ways are opening up, and there seems good reason to believe that our present estimates for man, although involving extrapolation, may with assurance be regarded as minimal ones, and of the right order of magnitude. Before this point could be arrived at it was necessary to carry out a vast amount of work in the genetics of lower organisms, and also to collect very considerable data from man, and to consider these in connexion with one another. An increasing attack along both lines will be necessary if we are to attain the knowledge we need for the adequate protection and the fostering of our most precious trust, our genetic heritage.

Annex 2

The Types of Mutation Produced at Known Gene Loci and the Possibility of Hitherto Unrecognized Mutations Being Induced Animal Population Irradiation Results and Work Needed[1]

It is commonly acceptable as a working hypothesis that ionizing radiations do not induce new types of mutation, but only raise the mutation rates of existing alleles. The basis of this assumption is partly theoretical and partly experimental. The theoretical argument rests on the fact that all living matter is continuously exposed to natural background radiation, and always has been so exposed; therefore, it is argued, any mutation which could be induced by ionizing radiation must already have been induced by natural background radiation at some time in the past; therefore no new type of mutation could be induced by man-made radiation. The experimental data, which are now extensive, do not disprove this; but in so far as it is essentially a negative hypothesis, and fails to specify the extent of either spontaneous or induced mutation, it is by its very nature not amenable to experimental test. Thus if in some experiment radiation exposure induces mutations of a type previously unknown, this can always be explained as nothing more than a manifestation of the limited nature of prior knowledge of spontaneous mutation; conversely, if exposure fails to induce mutations of a type previously known, that can always be explained as a manifestation of the finite nature of the experimental set-up. The hypothesis that ionizing radiations do not induce new types of mutation is therefore, like so many others in biology, unprovable and undisprovable. As such, it can only be of heuristic value; the extent of its value depends on our assessment of the extent to which it may be true, and the extent to which we are willing to use it as a guide in planning future action.

In point of fact, geneticists are willing to place so much faith in its validity that this hypothesis forms the basis of all present day estimates of the genetic hazard of ionizing radiation to man. It is therefore worth while to ask if circumstances can be visualized in which it might break down. The supposition underlying it is that man-made radiations do not differ in any essential respect from natural background radiations. In respect of dose-rate they extend far beyond the natural range, but we have no clear evidence of dose-rate thresholds for the induction of genetic effects. So far as present knowledge goes, it seems that linear energy transfer is the biologically most important characteristic of a radiation; and in this respect natural background radiation covers the whole known range, from the sparse ionization of naturally occurring gamma rays to the dense ionization produced by alpha particles and heavy cosmic nuclei. Thus there does not at present appear to be any obvious theoretical reason for expecting man-made radiations to induce alleles that were previously unknown. On the other hand, there is no theoretical basis for the converse supposition, namely that ionizing radiation can induce all known alleles; in fact, there is a certain amount of experimental evidence that it tends to induce especially the more extreme alleles at a locus.

It is worth noting that though this hypothesis has a theoretical basis which is probably valid for mutagenesis by ionizing radiations, the analogous hypothesis for chemical mutagenesis has none. There is no ground for postulating the natural occurrence in biological material of all chemical mutagens which might be synthesized in the laboratory. Furthermore, some chemical mutagens might be expected to have a relatively mild action, and induce subtle genetic changes, compared with the generally destructive action of ionizing radiation. Recent experimental work in this field, notably that of Fahmy & Fahmy (1956), supports an interpretation of this type. Furthermore, if (as seems probable) ionizing radiation is responsible for only about one-tenth of human spontaneous mutation, leaving nine-tenths to be accounted for, we should be unwise to ignore the possibility that chemical substances may be much more important than ionizing radiation as a cause of human mutation.

Thus far I have considered the gene only as the unit of mutation, its constancy between mutational events being implicit. But a gene is also a unit of action, its presence being recognizable only by its effect on the phenotype of an individual. Furthermore, the final effect of a gene, unlike the gene itself, may be extremely variable, depending upon the other allele at the same locus, the alleles at other loci and the mass of non-genetic factors, grouped together under the term

---

"environment". In no two individuals are the total genotype and the total environment identical, and therefore in no two individuals can the same allele be expected *a priori* to produce identical end effects. Variability of gene expression may be very great where the end effect is putatively remote from the primary gene product, with many morphological mutants; conversely it may be relatively slight where the effect observed is believed to be close to the primary gene product, as with the blood group antigens. In so far as the practices of civilization have wrought great changes in the macro and microenvironment of man, we must suppose that they have changed and are changing the expression of many human alleles.

Many systems can be invented for the classification of human genes, and which particular system is used will depend on the interests of the user. The population geneticist is interested primarily in the biological value of a genotype. He will therefore classify alleles according to their average effect on the fitness of their carriers, that is to say on the number of zygotes that will be contributed to the next generation by a zygote of the present generation. It will be a twofold classification, according as the allele is in the homozygous or heterozygous state. Mutant alleles are probably almost always disadvantageous to some extent when homozygous, but their action in heterozygotes may vary from severe detriment through neutrality to advantage. This fact divides them into two broad classes: those which are unconditionally disadvantageous, and those which are disadvantageous in some individuals but advantageous in others. The distinction is fundamental, for it determines the nature of the forces which will maintain the allele in the population and the frequency at which it will be maintained. An unconditionally detrimental allele will be maintained at a low frequency under the opposed action of mutation to the allele and natural selection against it. On the other hand, an allele which is advantageous in some individuals and disadvantageous in others will be maintained at a high frequency, depending on the degree of advantage or disadvantage in the various individuals. Mutation will play only a minor role, or even none at all, in determining the structure of the population in respect to alleles of this type. It is therefore of importance to any assessment of the genetical hazards of radiations to man to know whether alleles of this type are of common occurrence. Unfortunately it is a problem of exceptional inherent difficulty, because we may expect that the more easily recognized genes will largely be among those with notably detrimental effects; and, conversely, that the conditionally advantageous genes will be mainly among those with minor effects and that they may, for just this reason, be difficult to recognize.

This brings me to a point where I find it necessary to voice some misgivings which I have felt for a long time about one aspect of what might be called "genetical public relations". Soon after H. J. Muller's demonstration that X-rays have a mutagenic action it was realized that they present a genetic hazard to man. At that time genes were thought of as consisting mainly, if not entirely, of common, advantageous, wild-type alleles and rare, deleterious, mutant alleles. They were unconditionally good or bad. Mutation was viewed as a necessary evil; it was something which happened, without which the species would lack the heritable variation on which future evolution depends, but it introduced into the population a load of mutant alleles which had to be eliminated by processes of natural selection. Each mutational event implied the occurrence of another mutant allele to be eliminated sooner or later through the "genetic" death of some individual if equilibrium were to be maintained.

I do not think anyone seriously doubts that this is a reasonably accurate representation of the state of affairs in respect of grossly deleterious autosomal dominant or sex-lined genes such as retinoblastoma or haemophilia. On the other hand, I think may geneticists would now doubt whether this concept is valid for more than a relatively small proportion of all human genes. Clear-cut unconditionally deleterious oligogenes may be relative rarities. They may represent only one tail of a distribution; numerically they may come far behind the polygenes, each with an effect so small as to be virtually undetectable by the methods of classical genetics, yet together of major importance because they regulate the quantitatively variable characteristics of each species through which evolution must largely operate. Now the outstanding feature of almost any quantitative character is that it has a central optimum; the extremes in either direction appear to be at a disadvantage, in respect of biological fitness, compared with some intermediate phenotype. The theoretical interpretation is that heterozygotes for genes affecting a quantitative character have a greater

biological fitness than the corresponding homozygotes; and this implies that the mutation rate may be relatively unimportant in determining the gene frequency.

The above argument has been based mainly on theoretical considerations; but there is now a great mass of observational and experimental evidence that heterozygosity is the rule rather than the exception in wild populations. If any-one doubts it, he should re-read the writings of Dobzhansky and his co-workers on wild *Drosophila* populations, of Bruce Wallace on irradiated *Drosophila* populations and of Dunn on mouse populations; or he should try inbreeding any species that is normally crossbreeding.

In the face of all this I find it disconcerting that geneticists, when writing for the public, still often base their argument on an assertion that all mutation (or very nearly all) is harmful. I say it is disconcerting in the full knowledge that I use exactly the same argument when, as happens all too often nowadays, I have to give a talk on radiation hazards to an intelligent but gentically uninstructed audience. Perhaps its attraction is that it is a relatively easy argument to put over; or perhaps we use it because one can draw quantitative inferences about the genetic load due to some unconditionally deleterious human alleles, whereas at present it is almost impossible to speak quantitatively about human polygenic characters. But, whatever the reason, it is extremely important that we geneticists should not bind ourselves to the fact that unconditionally deleterious oligogenes may constitute only a small fraction of the human genome. Furthermore, I am not entirely happy that any science can be really healthy when it has one story for home consumption and another for the rest of mankind.

The necessity for using an argument such as this stems essentially from one fact we know something about mutation in man and experimental animals, but we know very little about the effect on a population in which mutation is induced. We know enough to be reasonably certain that the current theory of mendelian populations is over-simplified and unable to accommodate some essential features of real populations; but we have not yet got a satisfactory theory to put in its place. For the present there can be only one corollary; we must have more research on the genetic structure of populations ,in the hope that the nature of the facts will become clearer and will stimulate the development of a more complete theory. This theory would have to cover the origin and loss of variation in populatons its origin by spontaneous or artificially enhanced mutation and by environmental action, and its loss by natural or artificial selection.

There have been many genetic studies of wild populations. Though in most of them the object was to study the effects of natural selection, it is only rarely that direct evidence has been obtained that the effect observed really was due to this cause. Thus the spread of melanic forms of various species of moths in industrial areas has been observed for over a century; and it has been assumed throughout that the spread was due to a selective advantage of the melanic form, following an environmental change from the relatively clean agricultural to the sooty industrial economy; but it was only last year that Kettlewell (1955) was able to confirm the validity of this assumption, by direct observation of the numbers of moths of the various phenotypes taken by bird predators. It has also been a characteristic of studies of wild populations that, with few exceptions, the material studied has been polymorphic. This must have been due largely to subjective selection by the investigator, since a polymorphic population holds an obvious interest which a monomorphic population lacks. Nevertheless, where an apparently monomorphic population has been sufficiently closely observed, it has often proved to be polymorphic, even though the polymorphism may have been cryptic. Obvious examples are the populations of various *Drosophila* species studied by Dobzhansky and his school, (vide Wallace, 1954), and the mouse populations studied by L. C. Dunn (1953). Dunn's work is of especial interest, because it shows that mechanisms whereby coadapted blocks of genes could come into existence are not peculiar to *Drosophila*. The mechanism in the mouse differs from that in *Drosophila*, but the effects are the same: suppression of crossing over and selective advantage of the heterozygous genotype in which it has been suppressed, even at the cost of a high proportion of inviable homozygotes. His findings gain significance in the light of the recent demonstration by my colleague Dr. Mary Lyon, using an induced translocation, that the region of suppressed crossing over is at least five times as long as the short segment marked in Dunn's experiments.

The study of mutation and artificial selection in the laboratory and of natural selection in wild populations are three approaches to a much more difficult study, namely that of populations with mutation rates that have been enhanced by ioniz-

ing radiations or other mutagens. Nor must it be forgotten that ionizing radiations have other genetic effects besides mutagenesis; they increase crossing over, a fact which was known before their mutagenic action was discovered, and which may be of great importance in the study of polygenic systems.

Thus far few have attempted to work with irradiated animal populations. History dictated that one of the first studies in this field should be of a human population; but the genetical work of the Atomic Bomb Casualty Commission was almost foredoomed to failure, in the sense that it was very unlikely that statistically significant observations could have been made, even on the basis of the most extreme assumption, namely that all human "spontaneous" mutation is really induced by background radiation and that the doubling dose for men is consequently as low as 3 or 4r. In the event the results were, with one possible exception, negative; but all who are concerned with planning human radiation genetic studies in the future will owe a debt to Neel and his colleagues for doing the pioneer work in this field and exposing some of the problems (Neel *et al*,. 1953). The only other genetic studies of irradiated human populations of which I am aware are those of Crow (1955) and of Macht & Lawrence (1955); in each case the irradiated population consisted of radiologists. Here also the results were, in the main, negative; and the work suffered from the further limitation that it was impossible to estimate, even roughly, the radiation dose received.

There remain the experimental studies of irradiated animal populations. Of these there have been exceptionally few; and in almost all the experimental material has been *Drosophila melanogaster*. There are two reasons for this: first, a population to be maintained under known irradiation conditions must almost of necessity be kept in the laboratory; second, to guard against the possible effects of genetic drift, the effective breeding population should be at least of several hundred individuals. These requirements of laboratory culture and population size can be reconciled only by limiting the size of the individual animal. Subject to this limitation, *Drosophila melanogaster* is the obvious choice, being exceptionally well known genetically. We hope to develop techniques at Harwell for maintaining mouse populations in the laboratory, but I am doubtful whether it would be feasible to keep free-living populations of larger animals in an irradiated space. A possible solution might be to find an isolated wild colony and irradiate its habitat; this procedure would have the inherent defect, however, that one cannot be sure of obtaining a truly comparable control population; and in this work controls are a *sine qua non*.

If anything were needed to show how wide is the gap between observational fact and existing population genetic theory, the few published studies of irradiated *Drosophila* populations would do it. The various writers have given up any attempt to interpret their observations in terms of gene frequencies, contending themselves with observing what happens in their populations and attempting to interpret their observations in terms appropriate to the polygenic systems studied. Various combinations of selection type and mutational status have been used, and various types of foundation population. Bruce Wallace (1952) has observed the effects of natural selection on biological fiitness in populations originally derived from an inbred strain but now heterogenous, which were exposed to various levels of acute and chronic irradiation. Buzzati-Traverso (1954) likewise observed the effects of natural selection in irradiated populations; but here the foundation populations were inbred and the effects observed were egg-production and the incidence of the *non-spineless* phenotype due to modification of the genetic milieu in a homozygous *spineless* population. Clayton and Alan Robertson (1955) likewise used inbred foundation populations; they observed the variance of the number of abdominal bristles and the response to artificial selection for this character. Scossiroli (1954) selected for sternopleural hairs in an irradiated population which was genetically heterogenous but which had previously been selected by Mather without irradiation and had reached a plateau.

It is too early to attempt to draw general conclusions from these experiments, but some things are clear. Buzzati-Traverso's work shows that irradiation of an inbred population can release genetic variability in a character such as egg-production, which is one of the components of biological fitness, and can thereby enable natural selection to increase fitness. Scossiroli's work shows that irradiation can release genetic variability in a heterogeneous population which has reached a selection limit, and can thereby enable the limit to be surpassed. Bruce Wallace's work shows that populations can live success-

fully under conditions of irradiation in which a large proportion of their chromosomes carry gene combinations which are lethal when homozygous, but that some of these combinations may be advantageous when heterozygous. The work of Clayton and Robertson shows that the amount of genetic variability arising spontaneously through new mutation in each generation is only a minute fraction, perhaps a thousandth, of that normally present in a *Drosophila* population; and that a part only of the additional genetic variability released by irradiation may be available for selection.

Just what the full implications are for human genetics it is impossible at present to assess; but two conclusions seem inescapable. First, it is essential to extend work of this type and to cover other species, including mammals, with a much lower reproductive potential than *Drosophila;* the results might be very different in species where the female produced only ten young instead of hundreds and selection differentials were consequently lower. Second, we have no mandate from experimental fact to extend to the whole human genome the theoretical treatment of the genetic hazard of radiations that we now apply with a fair measure of confidence to grossly deleterious gene mutations. It follows that for the present we must limit quantitative assessment to this part of the hazard alone; and this implies that the first task of human genetics must be to identify as completely as possible that part of the social load which is due to genes in this class.

ANNEX 3

A DISCUSSION OF SOME OF THE PROBLEMS ACCOMPANYING AN INCREASE OF MUTATION RATES IN MENDELIAN POPULATIONS[1]

Problems arising from the exposure of man to irradiation are extremely numerous. They bear on many aspects of his health and his children's health. To the extent that the original exposure—medical or industrial—aims at improving man's welfare, he benefits, to the extent, however, that the exposure does him bodily harm or induces gene mutations that will harm his offspring, he suffers.

[1] Submitted by Dr. Bruce Wallace, Biological Laboratory, Long Island Biological Association, Cold Spring Harbor, Long Island, N. Y., USA.

The mutagenic effects of radiation pose problems of immediate concern to the geneticist. These problems are of three major types: the development of a theory of population genetics adequate for the formulation of predictions, the design of experiments capable of testing the theory and of supplying empirical values for various parameters, and the extrapolation of theory and experimental results to human populations.

The postulated role of mutations in Mendelian populations depends largely upon the basic concept one entertains regarding the genetic structure of populations. In the main, there exist two contrasting but not mutually exclusive concepts: the first is based upon the superiority of homozygous individuals; the second, upon the superiority of heterozygotes.

The first concept postulates that individuals of the highest possible fitness can be completely homozygous. Natural selection acting within a constant environment would favour these individuals and would tend toward the establishment of a population composed entirely of homozygous individuals. In such a population the individuals of each generation should, ideally, be identical and the individuals of one generation should be identical to those of the next. Mutations in a population such as this operate to frustrate the aims of natural selection. By definition, the new mutations are deleterious and, consequently, their constant formation prevents the population from reaching the level of fitness theoretically possible. Furthermore, under equilibrium conditions the deleterious effect of mutations on the population is a function of mutation rates and is independent of the harm done to any one individual by any one mutation. Theoretical treatments of this problem have been given by Haldane (1937), Crow (1952), and, in great detail by Muller (1950). Although no one actually believes that environmental conditions are constant or that the ideal population described above actually exists, the model is reasonable nevertheless if one assumes that near-equilibrium conditions exist at any moment and that genetic changes within populations occur slowly (see, for instance, Haldane, 1954).

The second concept assumes that even under constant environmental conditions the individual with the highest fitness is genetically heterozygous rather than homozygous. Furthermore, there need not be one ideal genotype but many. An ideal population of this sort would consist of individuals as phenotypically uniform as possible consistent with the demands of natural selection but these individuals would be genetically diverse. Similarly, individuals of one generation would not be genetically identical, even under ideal conditions, with those of the next. The selective coefficient of any gene in this type of population would be a function of the genetic situation prevailing within that population. Since the population consists of individuals of diverse genotypes, selection would be constantly shuffling gene frequencies and selective values simply because of the uncertainties associated with the formation of chance gene combinations. The details of this model have not been developed in a way comparable with the first; one can say, however, that gene frequencies under this model are primarily a function of selection and only secondarily a function of mutation rates.

These two concepts are not mutually exclusive. It may develop that one or the other is substantially correct. It may be that for some loci one is correct while for others the second applies. It is quite probable that different species differ in their genetic structure. Finally, at different times and in different places the genetic structure of a population may shift from one model to the other.

A few remarks may be made regarding the logic underlying these two concepts of population structure. Genes and chromosomes are the means by which information is passed from one generation to the next; in some cases they are the only means, in others this hereditary information is supplemented by the "spoken" word which allows individuals of one generation to communicate with those of the next. The first concept, that based on the superiority of homozygous individuals, stresses the accuracy of the transmitted information. In the absence of mutations and of environmental change, every individual of a generation would be supplied with precisely that information which has proven valuable in the past. There is no wastage through the formation of ill-adapted individuals. Furthermore, it is a moral system in that, under ideal conditions, every individual is his neighbour's equal. The second concept entails wastage; certain individuals must obtain hereditary information that is not perfectly accurate. In so far as this wastage can be equated with suffering (and it certainly can be considered in this way for human beings), the second concept is morally deficient.

What arguments, then, can be mustered to support the second concept, and to justify giving it serious consideration? First, to the extent that genes are semi-dominant, their frequencies are changed much more rapidly by the action of selection on heterozygous individuals than by that on rare homozygotes. Second, a gene that is beneficial through some semi-dominant effect need not be beneficial when hemozygous; the nature of these homozygous individuals is unimportant to the population at the time selection favours the heterozygotes. Third, the replacement of superior aa′ individuals by equally good a″a″ individuals requires that the allele a″ also be advantageous when heterozygous. Fourth, there are physiological reasons for doubting in some instances whether a single allele in homozygous individuals can actually duplicate the action of two contrasting alleles in heterozygotes.

One difficulty confronting the second concept is more apparent than real. It arises from the geneticist's inability to distinguish which of two alleles is a favourable dominant and which is a deleterious recessive (see Crow, 1952, footnote p. 285). A geneticist can detect gene effects by substitution only. Genetic changes within a population are determined by the sequence in which mutations occur. By completely ignoring the sequence of genetic change and by regarding the favourable dominant as "normal", one is forced to the absurd conclusion that the origin of each favourable dominant (or semi-dominant) lowers the fitness of the population and that the population regains its normal fitness only if the new dominant attains fixation in the population.

Finally, in reference to the first concept, I have mental reservations that stem from the assumed independence of the effect of the gene mutation on the population and the effect of the gene on individuals of the population. In other words, no matter how slight the deviation from the "normal" allele, the effect of a given class of mutant alleles is said to be proportional to mutation rate alone. In fact Muller (1948) mentions the possibility that small harmful mutations may be even worse for the population than fully lethal ones. I do not question the calculations that demonstrate this fact; I question the assumptions upon which the calculations are based and which result in a curve with such an abrupt break regardless of how infinitesimal the effect of the mutation might be.

The problems mentioned so far lie in the realm of theoretical speculations. They are problems one meets when attempting to visualize techniques employed by Mendelian populations in meeting the demands of existence, techniques compatible with the known facts of genetics. The second large class of problems arises in connection with the design of experiments aimed at testing the validity of theoretical models. Regardless of one's concept of the genetic structure of a population, obtaining experimental data to verify the concept or to furnish evidence regarding certain parameters is an overwhelming chore.

Information required for the manipulation of equations under the model that stresses homozygosity includes estimations of numbers of loci, total mutation rates, distributions of mutations in terms of their effects on various components of fitness (viability and fertility in particular), the distribution of deleterious mutations among individuals of a population, and dominance-recessive relationships. Information along these lines is being gathered, among other laboratories, at Oak Ridge and at the University of Indiana under the direction of Dr. Russell and of Professor Muller, respectively. I believe we all recognize the tremendous effort required to obtain this information.

In our laboratory we have taken what appears superficially to be a somewhat simpler approach: the simultaneous analysis of the genetic content of experimental populations of *D. melanogaster* in terms of genes affecting fitness and measures of fitness itself. The latter measure will be required for the final verification of one's concept of population structure regardless of which of the two one entertains. The chief difficulties in this approach lie in the estimation of fitness and in determining the amount of selection required to maintain this fitness. These difficulties are compounded by the necessity to limit one's studies to components of fitness and to carry out the analyses outside the population, outside even an experimental population. In studies of components of fitness one generally assumes that these components are to some degree correlated with one another and with their sum. Robertson (1955) has pointed out, though, that in a population at genetic equilibrium the components of fitness must be negatively correlated. This indicates that a technique for measuring total fitness must eventually be found if the role of mutations in populations is to be evaluated experimentally.

Difficulties associated with the determination of selection pressures within populations do not seem insurmountable at the moment. Specific genetic changes within populations offer one source of information—for instance, the increase in frequency of one particular mutation, the establishment of equilibrium frequencies, or the loss of mutations following the cessation of irradiation. Estimations of population size shed light on the extent of inter-progeny selection; that is, one can judge whether a population exists because a few parents leave many offspring or because many parents leave a few each. Furthermore, larval mortality rates can be altered substantially without changing the adult population size to any appreciable extent; manipulations of this sort will offer an approach to the study of intra-progeny selection.

The final group of problems deals with the extrapolation of theory and experimental findings to man. The first problem that comes to mind is the shift in emphasis demanded by the importance of man's intellect. In experimental material "fitness" is equated with the ability to live and to reproduce; the emphasis in eugenic studies on the differential fertility existing in relation to I. Q. and racial origins shows that the experimental concept of fitness is not completely acceptable for human populations. Furthermore, although a long life and a full life is highly desirable, length *per se* is not all-important. Although the pertinent facts lie outside the realm of genetics, I suspect that the change from a 60-hour to a 40-hour work week has added more pleasurable, livable years to the average working man's life than he has lost by way of industrial and automobile accidents. These and similar problems are concerned with values; although there may be a consensus of opinion regarding these matters, there are bound to be sharp disagreements between societies and persons and even sharp changes in the views held by the same individual at different times.

Additional problems arise, too, because man is a social animal. The two concepts of populations described earlier dealt with ideal individuals with the highest possible fitness; these concepts are applicable to populations in which, with the exception of mating, there is no interaction between individuals in determining the fitness of the population. Such concepts are inadequate for dealing with populations of social organisms in which the fitness of the population is a function not only of the fitness of the individual members but also of the interaction between individuals. It would seem that before one can approach the problem of the ideal genetic architecture of populations of social organisms, including man, one would have to solve the simpler problem of the ideal constellation of phenotypes. I do not recall having seen such an analysis for human populations.

The next problems to be discussed concern what may be described as experimental human ecology. The central problem concerns the extent by which the visible human population, or, better, the reproducing human population, differs from the initial population of fertilized eggs from which it came. How strong are the selective forces operating within human populations? Mortality figures are available for the post-natal and late pre-natal periods. Figures are undoubtedly available, too, for the proportion of individuals who remain childless throughout life. Good data concerning the mortality of individuals in the early post-fertilization periods are not available at the moment. Lacking, too, are indications of the extent to which this mortality and sterility (effective, if not actual, sterility) are selective; random elimination, of course, is ineffective in bringing about genetic changes within populations. Haldane (1954) has developed a method for estimating the intensity of selection that utilizes phenotypic measurements only; this method may prove valuable in the analysis of human populations. Other data that would shed light on the selective potentialities of human populations are those dealing with the rapidity with which resistance to certain diseases has spread within memory of man and the effectiveness of this newly acquired resistance; this information would need to include the price in terms of mortality that the affected populations paid while selection operated. Along these same lines, it would be of particular interest to determine the factors responsible for limiting the number of children per couple in many human societies. When the average number of offspring per pair falls irrevocably below two for any species, that species can no longer replace itself numerically from one generation to the next and extinction is inevitable. In some human communities the present average is but slightly above two. Since this average is determined by a combination of sociological and biological factors, some effort should be expended to determine

the actual biological limit for the number of offspring human couples can have.

If it should develop that selection is more effective in man than we have suspected, we must nevertheless be wary of those who claim that radiation will do no harm to the human species. The rate at which mutant genes enter the gene pool of a population must equal the rate at which they leave. Mutant genes leave the gene pool by the effective elimination of individuals either through death, sterility, failure to reproduce, or a tendency to reproduce at a reduced rate. Effective elimination of individuals means, for human beings, that one individual is placed at a disadvantage relative to another; in many instances the "elimination" is accompanied by mental or physical suffering. Therefore, regardless of the ability or inability of "natural" selection within human populations to forestall extinction or to maintain the "fitness" of the population as a whole, we are still forced to the conclusion that every exposure of individuals to irradiation must be justifiable in terms of the beneficial effects that exposure confers either to the exposed individual or to the population as a whole. In the light of known effects of radiation it is impossible to defend unnecessary or unnecessarily high exposures.

ANNEX 4

THE EXPOSURE OF MAN TO IONIZING RADIATIONS, WITH SPECIAL REFERENCE TO POSSIBLE GENETIC EFFECTS [1]

The purpose of this review is to show which generally occurring sources of ionizing radiation may at present be relevant and which may be irrelevant in discussing the effects of ionizing radiations on man.

We have to consider the direct effects on human tissues, as well as the indirect effects due to mutations of somatic cells, causing harmful effects to the individual himself, or of germ cells. The latter may either involve risks for the offspring already in the next generation, consequently being of interest to the individual himself, or may—with irradiation of a large number of inhabitants—constitute a long-term problem in the entire population.

The present sources of ionizing radiations which are of interest in these connexions include the following:

Natural sources of radiation

1. Sources of cosmic radiation.
2. The natural radioactive elements, particularly radium, thorium and potassium in the earth crust.
3. The natural content of radioactive elements in man.

Man-made sources of radiation

4. Radioactive material and technical arrangements producing radiation (X-ray tubes, other particle accelerators and nuclear reactors) used under such circumstances that the user generally is aware of the presence of the radiation (e. g. in education, science, medicine, and industry).
5. Sources of radiation used for purposes in which, as a rule, only the specialist is aware of the presence of ionizing radiation (e. g. radioactive luminous compounds on watches and other articles for common use, television sets, etc.).
6. Radioactive elements artificially distributed in nature.

THE MAXIMUM PERMISSIBLE LEVELS OF IONIZING RADIATION FOR INDIVIDUALS AND LARGE POPULATIONS

Before treating the different sources of radiation which contribute to a larger or smaller extent in producing the present level of ionizing radiation in man, a brief account of the maximum permissible doses recommended may be given.

The International Commission on Radiological Protection (ICRP) at its session in Geneva, April 1956, decided to make the following additions to their earlier recommendations:

* * * * * * *

A *controlled* area is one in which the occupational exposure of personnel to radiation or radioactive material is under the supervision of a radiation safety officer.

For such personnel the maximum permissible levels of exposure are those specified for occupational exposure. In the case of prolonged exposure to radiation from external sources the maximum permissible levels for occupational exposure are represented by weekly doses of 600 mrem in the skin and 300 mrem in the blood-forming organs, the gonads and the lenses of the eyes.

* * * * * * *

For any person in any place outside of controlled areas the maximum permissible levels of exposure of 10% of the occupational exposure levels.

* * * * * * *

When genetic aspects of the effects of radiation are considered, the dose received by the whole population is of importance. Scientific data derived from human as distinct from experimental animal populations are so scanty that no precise permissible dose for a population can, at present, be set. The available information is being assessed by the Commission and other groups including geneticists. Until general agreement is reached, it is prudent to limit the dose of radiation received by gametes from all sources additional to the natural background to an amount of the order of the natural background in presently inhabited regions of the earth.

* * * * * * *

The recommended maximum permissible weekly doses and the modified values for special circumstances, permit a desirable degree of flexibility for their application. In practice it has been found that in order not to exceed these maximum limits and also to comply with the general recommendations of the Commission "that exposure to radiation be kept at the lowest practicable level in all cases" a considerable factor of safety must be allowed in the design of protective devices and operating procedures. Therefore, under present conditions, it is expected that the average yearly occupational dose actually received by an occupationally exposed person would be about 5 rems and the accumulated dose in the employment period up to 30 years of age would be about 50 rems. Accordingly, the Committee recommends continuation of the present conservative practice as regards doses actually received by occupationally exposed personnel, to keep the accumulated dose as low as practicable especially up to age 30.

In the report of the Medical Research Council (MRC)[a] "The Hazards to Man of Nuclear and Allied Radiations," issued in June 1956, the following conclusions are drawn:

* * * * * * *

(2) Dose levels to the individual: (a) In conditions involving persistent exposure to ionizing radiations, the present standard, recommended by the International Commission on Radiological Protection, that the dose received shall not exceed 0.3 r weekly averaged over any period of 13 consecutive weeks, should, for the present, continue to be accepted.

(b) During his whole lifetime, an individual should not be allowed to accumulate more than 200 r of "whole-body" radiation, in addition to that received from the natural background, and this allowance should be spread over tens of years; but every endeavour should be made to keep the level of exposure as low as possible.

(c) An individual should not be allowed to accumulate more than 50 r of radiation to the gonads, in addition to that received from the natural

[a] Medical Research Council, "The Hazards to Man of Nuclear and Allied Radiations", London, 1956.

background, from conception to the age of 30 years; and this allowance should not apply to more than one-fiftieth of the total population of this country.

(3) Dose level to the population: Those responsible for authorizing the development and use of sources of ionizing radiation should be advised that the upper limit which future knowledge may set to the total dose of extra radiation which may be received by the population as a whole, is not likely to be more than twice the dose which is already received from the natural background; the recommended figure may indeed be appreciably lower than this.

* * * * * * *

In the report of the National Academy of Sciences in Washington (NAS)[8] "The Biological Effects of Atomic Radiation" the following recommendations are made.

Thus we recommend:

(C) That for the present it be accepted as a uniform national standard that X-ray installations (medical and non-medical), power installations, disposal of radioactive wastes, experimental installations, testing of weapons, and all other humanly controllable sources of radiations be so restricted that members of our general population shall not receive from such sources an average of more than 10 roentgens, in addition to background, of ionizing radiation as a total accumulated dose to the reproductive cells from conception to age 30.

* * * * * * *

(E) That individual persons not receive more than a total accumulated dose to the reproductive cells of 50 roentgens up to age 30 years (by which age, on the average, over half of the children will have been born), and not more than 50 roentgens additional up to age 40 (by which time about nine tenths of their children will have been born).

Obviously it is generally agreed that at present it is desirable to limit the doses received by the gonads of individuals to less than 5 roentgens per year and 50 roentgens before 30 years of age and that the average dose to the gonads of the population as a whole should be kept very low; of the order of the natural background (ICRP) twice this level (MRC) or to 10 r before 30 years of age (NAS). The difference in these figures is not very important as their order of magnitude will in practice be about the same.

According to our present knowledge it seems likely that a dose of 30—80 r will (according to MRC) double the natural mutation rate in man, which is probably only to a minor fraction (perhaps about 10%) caused by ionizing radiations. The rest of the natural mutations will, to an unknown extent, be due to chemicals and to the thermal movements of the molecules. It seems to be highly desirable for mutations induced by chemicals in particular to be investigated, in order to elucidate the relative role of radiation-induced mutations.

The recommendations made by the organizations quoted above are as regards the whole population based mainly on the natural level of ionizing radiation. It is not the place here to discuss whether this is a corerct starting point, nor whether or not the maximum permissible dose levels recommended are reasonable. They are fixed after careful consideration based on our present, unfortunately very incomplete knowledge of the biological effects of small radiation doses, but are agreed to by specialists in biology, genetics, haematology, physics, and radiology having long experience in radiation protection both on the research and on the practical side.

With respect to the risks of injurious effects on man one matter may, however, be stressed. There must always be a reasonable ratio between what can be gained by the use of ionizing radiation and the risks of its injurious effects. The use in medicine of ionizing radiation for examination and treatment of patients therefore occupies an exceptional position, that has not always been taken into account in recent years, in the discussion of the problems of the general irradiation of mankind. There must certainly be a sound balance between the benefits of a good health service and the risks to the patients with respect to onset of malignant disease or genetic damage of which, however, we at present do not know very much.

NATURAL SOURCES OF IONIZING RADIATION

Cosmic radiation

The cosmic radiations produce the doses shown in Table I.

The values for O—4000 m have been calculated from the work of Compton and co-workers (Fig. 1) taking into consideration that some reduction due to absorption may be justified indoors, and the values for 6000—18,000 m from Millican and co-workers (Fig. 2). The values are fairly approximate, as there are many factors which are difficult to allow for at the higher altitudes, especially with regard to the unknown relative biological effectiveness of heavy nuclei rays.

Variations with time.—Major variations in cosmic radiation occur during short periods only, and the few occassions associated with an appreciable increase are so rare and of such short duration that the doses caused by cosmic radiation for a certain altitude and geomagnetic latitude may at the earth surface be regarded from the practical point of view as constant. A record of the variation in the cosmic radiation on February 23, 1956, is shown in Fig. 3. This is one of the occasions on which an extraordinary increase was observed. The dose due to this temporary increase was, at sea level, less than 0.03 millirem.

As to the long-term variations, it seems highly unlikely that any major variations in cosmic radiation have taken place during the last 2,000 years.

Variations with site.—The maximum variation between different places on the earth surface, excluding mountains of more than 4000 m high, is about 2 r per 30 years.

Doses to individuals.—The doses to individuals may be of importance for very high altitudes. The present development of communication by air makes it necessary to take into account the fact that, at very high altitudes, the maximum permissible dose of 50 rem may especially at high geomagnetic latitude already be exceeded if on the average some 10 hours per week are spent at this altitude during 10 years, which might well be possible for future personnel in aircraft. The increase in cosmic radiation on February 23 may perhaps at altitudes of 20,000 metres correspond to a dose of less than some tenths of 1 rem obtained during a few hours, therefore probably being of limited biological significance.

Doses to large populations.—The contribution to the irradiation of large population groups (>100,000) varies between 0.7 and 2.7 r or approximately between 1 and 3 rem per 30 years.

The fact that an appreciable part of the radiation can be screened off by reasonable quantities of material may be of certain value for judging the risk for stratosphere and intersteller traffic. Investigations of the biological effects of cosmic radiation at very high altitudes are however desirable, because of the lack of knowledge as to the RBE values for heavy nuclei radiations.

Natural external γ radiation

The external γ radiation in nature varies with the radium, thorium, and potassium content of the ground and of the building material in houses. The γ dose in free air produced above level ground can be calculated according to the simple formulae:[1]

Radium: dose in r per 30 years	$0.57 \cdot 10^{12} . s(Ra)$
Uranium: dose in r per 30 years	$0.20 \cdot 10^{6} . s(U)$
Thorium: dose in r per 30 years	$0.094 \cdot 10^{6} . s(Th)$
Potassium: dose in r per 30 years	$41 . s(K39)$

in which s(Ra), s(U), s(Th) and s(K39) are the contents of radium, uranium, thorium, and potassium in g element per g substance of the ground.

To obtain an estimate of the dose to the gonads in rad,[4] the doses in free air have to be multiplied by a factor of 0.5 for women and 0.7 for men (1) or on the average 0.6, to account for the absorption in the shielding part of the body. The same factor may be approximately applicable to most of the other organs For the skeleton, the factor might be considered on the average, to be about 0.8.

The doses due to natural γ radiation over ground containing various minerals are given in Table II, and the dose in dwellings in Sweden (1) are seen from Table III and Fig. 4. These are in good agreement with the few observations in other countries.

[4] 1 rad corresponds to a dose of about 1.07 r in soft tissue.

The γ radiation from the ground is absorbed by snow, as seen from Fig. 5. A snow cover of 40 cm depth and of medium volume weight absorbs about 50% of the γ radiation from the ground.

A factor of considerable importance is the relation between the time spent indoors and out of doors. Here, it is assumed that on an average in large population groups ¼ of the life is spent out of doors.

As an additional contribution to the irradiation of man from natural radioactive elements in the earth crust, the radon and thoron of the air may play an important role in special cases. In general, the content of these elements in the air is too small to contribute to the dose received by the human body by more than a few percent. In some places and during some periods, this content can be fairly high, for instance in rooms where water of high radon concentration is used or the ventilation is insufficient, (1) in cellars where radon and thoron comes up from the earth, and in large cities during calm weather. (2) Such cases seem only occasionally to have been investigated. It would probably be worth while to make more systematic studies in this field. At present, these sources of natural radiation are too little known to be treated in this survey and will therefore be disregarded, although it is possible that they are of significance for the irradiation of the pulmonary system of a comparatively great number of individuals living in certain areas.

Variation with time.—The average annual dose to human beings due to natural sources has probably been of roughly the same magnitude during the present geological period. A slight decrease in the radiation occurred when man learned to use wood for building houses, and stopped living in earthen huts or in rocks where the amount of radon in the air was sometimes probably quite high. An increase subsequently took place again with the use of bricks and concrete as building materials, and when people moved to cities where material containing minerals more frequently comprise the surrounding material.

Another factor which may have caused a reduction in the environmental γ radiation for some populations may have occurred during the ice periods followed by certain areas covered by ice and snow during a greater part of the year than today. As already shown the snow causes an absorption of the γ radiation from the ground which appreciably reduces the irradiation out of doors, and produces a seasonal variation (see Fig. 6) in the irradiation of large population groups, especially those living outside the cities.

Variation with site.—As a rule, the difference in the level of natural γ radiation in different parts of the world is probably not very large. Even over areas containing rich uranium or thorium ores, the γ doses to the inhabitants only in rare cases exceed a few times the normal level. This is because the ores are generally very unevenly distributed both in rocks and sands, and are often covered or surrounded by material of normal radioactivity. The inhabitants moving over the area in question might thus, on an average, be exposed to doses which are much lower than could be conceived. This experience based on observations in Sweden needs further verification, but will probably be found to apply to most population groups throughout the world.

The doses of γ radiation to persons living in places more or less permanently covered by deep ice or snow, and those spending most of their time at sea, are generally very small. Here, the amount of γ radiation from the earth is often so minute that it can be entirely disregarded in comparison with the radiation from other natural sources. Recent investigations of the radiation level on wooden and iron vessels of different size have shown that the γ radiation already at a few metres distance from a granite quai is entirely negligible.

In Table IV some observations of natural γ radiation in Sweden are compared with the results of similar investigations in the UK and USA.

In view of the statements in the aforegoing with respect to the average doses received by individuals, it would be of interest to carry out long term measurements by means of personal monitoring, in order to arrive at reliable data regarding the doses actually received.

The natural content of radioactive elements in man

In areas where the radium content of drinking water and food is not exceptionally high, the potassium content of human tissue is the main source of internal irradiation (see Fig. 7). The doses in rad due to the amount of potassium 40 (0.012% in natural potassium) in some human organs is shown in Table V. With respect to some tissues, particularly bone, the data of different authors vary considerably.

The content of carbon 14 and radon contributes about 5 and 10%, respectively, of the average potassium radiation.

According to measurements by Hursh & Gates (3) and recently by Sievert & Hultqvist (4) (Fig. 8), the radium content of the ekeleton is probably less than $0.3 \cdot 10^{-9}$ g, in areas with a radium content in the water of less than 0.2 $\mu\mu$ C per litre. According to Spiers (MRC), the mean dose to the osteocytes is about 6 rem per 30 years for $0.5 \cdot 10^{-9}$ g total radium body burden. The radium amount is, however, very unevenly distributed in the skeleton, and the dose significant for the production of osteosarcoma therefore seems to be extremely difficult to assess.

The *variation with time and site* in the natural internal irradiation is mainly a question of the variations in the radium content of water and food and of the radon in the air. Referring to what has already been said, it may be stated that there are not at present sufficient data available to give any reliable figures for different areas in the world. This also applies to the problem of the natural radioactive elements taken up in the pulmonary system. With respect to these matters, references can be made to a recent publication by Hultqvist (loc. cit.) in which an extensive bibliography is given.

The common limits of the doses to large population groups (>100,000) and to individuals from natural radiations are collected in Table VI.

MAN-MADE SOURCES OF IONIZING RADIATIONS

Radioactive material and technical arrangements producing ionizing radiation used under such circumstances that the user is generally aware of the presence of the radiation

Here, *occupational exposure* and *exposure of patients* undergoing treatment or investigation in radiology are the two matters to be considered.

The doses received by those carrying out work with ionizing radiation in education, science, medicine, technics, and industry are in most cases small, as the personnel can generally be adequately well protected. Furthermore, in all work where patients are not involved, there is no reason to permit irradiation which can in any way cause ill-effects. Here, the maximum permissible levels for individuals and large population groups are exceeded in rare cases only.

In radiology, especially some procedures in γ-ray therapy and in examinations using X rays, circumstances do not always permit entirely satisfactory protection of doctors and personnel. Here, the individual dose will sometimes be close to the maximum permissible levels, or even occasionally exceed them.

The occupational doses contribute to the radiation per capita of whole populations with an amount which in the UK (MRC) has been estimated at about 2.5 r per year as an average for about 14,000 people in research, medical and industrial work, and at about 0.4 r per year for about 7000 people in atomic energy work. Altogether, the average gonad dose per capita due to occupational exposure is estimated at 0.0016 r per year or, if 10 years is supposed to be the average period of work before reproduction, the relevant average gonad dose for the whole population may be less than 0.02 r before 30 years of age. An estimate of the corresponding figure for Sweden has given a considerably lower figure.

The occupational dose is apparently over the whole world attributed mainly to medical radiology, but is presumably very uncertain. It seems, however, that occupational irradiation does not at present contribute to the gonad dose of whole populations with any appreciable amount.

The doses received by patients undergoing treatment and examination by means of ionizing radiations, on the other hand, are of decisive importance, since they contribute by far the largest exposure of the population to man-made sources of radiation. In Germany, France, Sweden, the UK, and the USA, investigations have been carried out in order to ascertain the doses to the patients during various types of radiologic procedures. Numerous publications are available but up to now estimations to find a correct figure for the present average dose to the whole population due to the irradiation of patients have been made only in Sweden, the UK, and the USA. The results are that the average gonad dose per capita to the patients examined seems to be of the magnitude of 1–3 r in 30 years. The reliability of these figures has been much discussed, and it seems advisable to await further investigations based on radiation measurements and some sort of sampling method, before accepting any definite figures. It is nevertheless highly probable that the order of magnitude of the figures quoted is correct, since the estimations were made independently in three different countries.

Sources of radiation used for purposes in which, as a rule, only the specialist is aware of the present of ionizing radiation

At present, we are faced in this field with only a few matters of minor significance. The average gonad dose from luminous compounds in watches is found in the UK (MRC) to contribute to the average gonad dose by 0.001 r per year, and the radiation from television sets to a still more insignificant dose.

In the future development of atomic energy it seems highly probable, however, that the use of radioisotopes for various purposes will change the situation, and constitute a new problem by the distribution in the community of a large number of small radiation sources, each being completely harmless individually, but collectively raising the level of irradiation of the population.

Artificial radioactive elements distributed in nature

WHO and the study group which it has convened are concerned with the peaceful use of atomic energy and the effects of, for instance, radioactive waste disposal from such peaceful uses. However, it is essential to take into consideration the evidence available from atomic weapon tests since the problems in the field of artificial radioactive elements distributed in nature are at the present time mainly related to fallout from these tests. The dose due to the external γ radiation from fallout may at present (December 1956) be disregarded in comparison with the internal dose.

If the fallout in the vicinity of the test area and the effects of radiation during the first few days after the explosion are disregarded, two different effects may be of interest. One is caused by mixed fission products of medium half-life (a few days to less than one year), the other by the fission products of long half life, particularly Sr 90 (28 years) and Cs 137 (33 years).

Fission products of medium half-life are very unevenly distributed over the world after an atomic explosion. Here, meteorological circumstances play a most important role, since a jet stream, a cold or warm front causing turbulence in the atmosphere, and rain or snowfall can lead to a concentration of the radioactive material in some areas even at a great distance (several thousand kilometres) from the explosion.

A typical example of such an effect is given in Fig. 9, showing the γ radiation recorded during about one month in the four northernmost places indicated in Fig. 3b. The increase in the γ radiation occurred about five days after an atomic bomb test. It is obvious from these observations that a comparatively narrow set of stations is required to give an adequate picture of the distribution.

It has been shown by recent measurements of the γ radiation from large samples of foodstuffs in Sweden that most of our food today (milk, beef, corn and vegetables) now contains artificial radioactive elements, in many cases greatly exceeding the K 40 radiation level of animals and plants. As an example, a decay curve obtained from powdered milk is shown in Fig. 10.

After some bomb tests J 131 is easily detectable in the thyroid of growing cattle. The content of this element in Swedish cattle during September–October 1956 is shown in Fig. 11. The maximum dose per week was here 0.04 rad, or about 20 times the dose due to the average natural radiation, which can be considered to be about 0.002 rad per week. It is to be noted that the effects demonstrated in Figs. 10 and 11 are due mainly to atomic bomb tests in August and September 1956, but that even before that time the foodstuffs were contaminated to an easily detectable extent, partly owing to medium half-life elements.

It is impossible to estimate today what doses have been received by populations in different parts of the world from mixed fission products. In comparison with the doses from the fallout of Sr 90 and Cs 137, the mixed fission products may in many cases give smaller doses calculated over a long period. It must, however, be borne in mind, that many biological effects are dependent—perhaps more than we know at present—on the intensity of the radiation. Often there is a threshold to be exceeded before a biological effect is obtained. Our knowledge of the effects of small doses over long periods is very scanty and we cannot as yet be sure that the time-intensity factor can be disregarded, even with respect to genetic effects.

The fallout of Sr 90 and Cc 37 has been carefully studied during the past years. These elements are probably comparatively evenly distributed over the whole world (with the possible exception of the polar regions). Large amounts of these elements remain in the upper atmosphere and will successively contribute to an increase in their present abundance on the earth surface by a factor of 3–5, even if the firing of atom bombs is stopped. The incorporation of Sr 90 into the skeleton may, in places where the calcium content of the soil is small, be regarded as important.

It does not yet seem possible to estimate the doses to human tissue due to fall-out, nor their distribution in time, which are necessary data for judging its possible biologic significance. Experience during the past year is, however, likely to raise doubts as to the lack of biologic importance to the tests of nuclear weapons, at any rate if they are continued on the present scale.

It is extremely difficult to predict what will in the future be the most important sources of radiation caused by artificial radioactive elements distributed in nature. There is reason to believe that the problems of disposal of radioactive wastes will be satisfactorily solved, and that precautions in the handling and use of radioactive material will be adequate, but accidents and unforeseen events may gradually spread radioactive substances of medium and long half-life beyond control. These radioactive materials will follow unknown paths, and may be harmful to mankind in ways that will become known to us only after long experience.

ANNEX 5

DETECTION OF INDUCED MUTATIONS IN OFFSPRING OF IRRADIATED PARENTS [1]

THE PROBLEM OF THE GONAD DOSE

Among the various sources of ionizing radiation, apparatus for radiodiagnosis and radiotherapy today represents the main contribution of man to the increase in background radiation.

Radiodiagnosis, which is being carried out more and more frequently every year in all the developed countries, at present plays a dominant role in this connexion. Ranging as it does from the radiographs and radioscopies called for by some pathological condition, to the periodic radiographs of the whole skeleton used in studying the growth of normal children, the field of exploratory radiology now covers an extremely large proportion of the population; for example, in France, all children of school age are submitted yearly to systematic radiographic examination.

While there can be no doubt that most radiodiagnostic examinations affect the gonads only very slightly, all examinations of this type which involve the pelvic region may have genetic effects (for example, gynaecological and obstetrical examinations).

One has only to consult the appropriate tables, such as the one drawn up by Plough,[2] to see that radioscopy may involve very high doses; for example, 10 to 20 r per minute for a gastro-intestinal radioscopy. While techniques such as radiocinematography, which, happily, are not used very extensively, are much more harmful, since they involve even higher doses. Several authors have attempted to calculate the mean gonad dose, on the basis of isodose curves, for whole populations. The estimates vary according to the author, but, in general, the gonad dose may be taken as being of the order of one roentgen; in other words, it represents a very considerable fraction of the quantity of natural radiation to which we are inevitably exposed.

Be this as it may, these estimates are based on the assumption that the radiation emitted by such apparatus is of known quality and that the methods employed in its application are standardized, which is very far from being the case. In fact, considering that radioscopic apparatus, often poorly shielded, is to be found more and more frequently in the consulting-rooms of general practitioners, one is justified in concluding that a very high proportion of radioscopic examinations are being carried out by physicians with no formal training in radiology.

In the opinion of the writer and his colleague, Professor R. Turpin, it would be desirable to obtain, by means of surveys among general practitioners as well as in hospitals, an experimental estimate of the gonad dose involved in any given radiological examination, under the actual conditions in which the said examination is carried out. Such surveys would make it possible to check the validity of the extrapolations at present in use.

A simple method would be to place micro-counters—or, perhaps even better, small films of the type used in atomic plants—in contact with the genital organs of all persons examined.

Even if such surveys were to result only in an increase in the precautions taken by those using X-ray apparatus, they would have partially fulfilled their purpose.

Radiotherapy certainly represents a much smaller risk from the genetic point of view, on the one hand because it is carried out by specialists, and on the other because in most cases the people concerned are elderly. Nevertheless, on examining the statistics of the radiotherapeutic services of the Paris hospitals, Turpin, Lejeune & Rethore [3] found that among 238,800 case-histories there were 4.428 cases of pelvic irradiation of adults under 35 years of age. The proportion of the total—about 2%—is, of course, low, but it does represent cases in which the radiation has impinged directly on the gonads of subjects who are still young enough to reproduce.

Although the calculation of the gonad dose is much more reliable in radiotherapy than in radiodiagnosis, direct determination during all forms of treat-

---

[1] Submitted by Dr. J. Lejeune, Chargé de Recherche au Centre National de la Recherche scientifique, Paris, France.

[2] Plough (1952) Nucleonics, 10, 17.

[3] Turpin, R., Lejeune, J. & Rethore, M. O. (1956), Etude de la descendance de sujets traités par radiothérapie pelvienne. Note préliminaire (paper presented at the First International Congress of Human Genetics, Copenhagen; unpublished).

ment (even extra-pelvic), by means of films or micro-counters placed in contact with the scrotum or in the vaginal fornix, would also be very desirable.

It follows from the foregoing considerations that the accuracy of an estimate of the mean gonad dose received in 30 years by nubile subjects should be checked by random sampling to determine the dose actually received under various examination conditions. It should be noted, however, that such work will be useless if it is not accompanied by systematic recording of the doses received by every individual in the population.

One method of obtaining systematic records, though perhaps a little startling, has already proved its worth. It entails treating the administration of X-rays in the same way as that of morphine for example, by providing all owners of X-ray apparatus with a counterfoil book (of the type used for prescribing narcotics), in which every radiological operation should be recorded and the following particulars given: name, age, and address of patients; reason for the examination, area examined; and details required for calculation of the dose (e. g., kilovolts, millicuries, type of filter, size of beam, etc.).

In practice, this form of registration would probably involve very considerable difficulties, but the increasing socialization of medicine would probably make it feasible for a known fraction of all radiological operations and would certainly draw the attention of the medical profession to a danger of which it is but little aware at the present time.

METHODS FOR DETECTION OF MUTATIONS INDUCED IN OFFSPRING OF IRRADIATED SUBJECTS

Since human geneticists cannot employ methods such as those used for *Drosophila,* they have to resort to statistical comparison of two populations of children supposedly identical in all respects save the dose of roentgens received by the gonads of their parents.

(a) *The study of abnormalities and malformations* may reveal an increase in frequency in the progeny of the irradiated group. This increase could be considered to be linked with the appearance of unfavourable dominant mutations. Although probably reliable in the case of definite genetic syndromes such as achondroplasia, this method is much less precise in respect of congenital abnormalities as a whole, since the latter are affected by extremely varied factors (age of mother, parity, etc.). However, if sufficient data are to be obtained to make it possible to draw conclusions, all abnormalities must be considered.

(b) *The study of the frequency of sex-linked recessive diseases* in the sons of irradiated mothers, although theoretically possible, necessitates such a large number of observations that it has not been undertaken.

(c) *The production of lethal genes* can be more easily detected. The most serious effect, sterility, is the one most generally known, but measurement of sterility or even of subfertility in man is extremely difficult. As has been remarked elsewhere (Turpin & Lejeune),[4] the actual fertility of civilized populations is hardly a third of the potential fertility of non-malthusian societies, which greatly diminishes the possibility of demonstrating the effects of sterility.

On the other hand, it is logical to expect the production of dominant lethals to bring about an increase in the frequency of miscarriages, which is difficult to establish, and of stillbirths, which can be obtained with much greater accuracy.

It is, however, essentially in the X-chromosome that the lethal genes can be detected, through a study of the sex ratio. Owing to the chromosomal structure of sex, the X-linked lethal mutations appear in different forms according to the sex of the irradiated parent. Thus, in the offspring of a woman exposed to radiation, dominant lethal mutations linked to the sex chromosome have no effect on the sex ratio, whereas sex-linked recessives bring about a deficit of boys. The contrary is true of men, in whose progeny only the dominant lethals manifest themselves by bringing about a deficit of girls.

If we call "n" the average number of dominant lethals linked to the X-chromosome in the offspring of men who have received a given dose of roentgens, then the following simple equation should apply:

$$\text{frequency of surviving daughters} = \frac{\quad}{\text{number expected}} \times e^{-n},$$

[4] Turpin, R. & Lejeune, J. (1955), Bull. Acad. nat. Méd. (Paris), No. 5/6, p. 104.

since the number of mutable loci in the X-chromosome should be large enough for the distribution to be of the Poisson type. Moreover, since it may be taken as a first approximation that this average number, n, should be identical for all the chromosomes, the autosomally viable zygotes represent a fraction of the total fertilized ova roughly equal to $(e^{-n})^{m}$, and it is in this fraction alone that it will be possible to observe a disturbance of the sex ratio.

Similar reasoning can be applied to the case of the offspring of irradiated women, bearing in mind the fact of that there is a relationship between the frequency of the dominant and the recessive lethals.

Since, in theory, the parameter n bears a linear relationship to the roentgen dose received, and since our estimates of the gonad dose are very approximate, there is probably a fairly strong correlation between the actual fertility of the parents after irradiation and the deviation of the sex ratio observed in their progeny. In other words, the most pronounced variations in the sex ratio would be shown by the offspring of parents who are almost sterile owing to the irradiation of one of them (for example, couples who have only one child).

It follows from the above that, in the absence of an accurate estimate of the gonad dose, an overall study of the sex ratio of all children born of an irradiated father or mother may, if it does not take into account the number of siblings born after treatment, result in the masking of the phenomenon by a "dilution effect", caused by the very numerous siblings who are the issue of a parent relatively slightly affected.

Further, the problem of control samples can only be correctly solved by comparing children born before and after treatment of the same irradiated parent and thus eliminating any genetic factor due to the couple itself, as well as the possible influence of siblings of one sex only.

Finally, and bearing in mind the above limitations, it would seem that the sex ratio is the most sensitive touchstone for detecting the production of lethal mutations in the first generation of children born of irradiated parents.

INFORMATION AVAILABLE AT PRESENT

Relatively few direct investigations of the influence of irradiation have been carried out and the writer will mention them in succession here, under the headings of the three main characteristics referred to earlier: frequency of abnormalities, frequency of miscarriages and stillbirths, and variations in the sex ratio.

(a) *Frequency of abnormalities*

Murphy & Goldstein[5] and Maurer[6] have published statistics on the offspring of women treated with X-rays or radium in the pelvic region. Unfortunately, neither of these papers can be considered very satisfactory, owing to the lack of detail concerning the families, on the one hand, and the absence of any controls, on the other.

Two recent papers cast more light on this question. In 1953, Neel et al.,[7] on studying the offspring of the survivors of the atomic bombing of Nagasaki and Hiroshima, did not find any increase in the frequency of serious abnormalities. While Macht & Lawrence[8] on comparing the children of fathers who were radiologists with those whose fathers were medical specialists not exposed to ionization risks, found a significant overall increase in abnormalities among the progeny of the radiologists. Unfortunately, the latter authors on the one hand included as abnormalities syndromes of a very varied and sometimes quite unsuitable nature (foetal erythroblastosis, for example) and on the other accepted the diagnosis made by the parents themselves, who, though admittedly physicians, clearly lacked the necessary objectivity. These considerations greatly limit the significance of the conclusions drawn by Macht & Lawrence, but it is only fair to stress that if, from the authors' data, those relating only to congenital forms of heart disease are selected, the increase pointed out among the progeny of the radiologists remains statistically significant.

(b) *Frequency of miscarriages and stillbirths*

Macht & Lawrence[8] mention a non-significant increase in the overall frequency of stillbirths plus miscarriages, while Neel et al.[7] report a non-significant

increase in the frequency of stillbirths. Finally, Crow,[9] who studied the offspring of American radiologists through a survey, by questionnaire, which was carried out along lines similar to those followed by Macht & Lawrence, has also reported a slight and non-significant increase in foetal mortality among the progeny of irradiated fathers.

All in all, although the published data agree fairly well on this point, they cannot strictly be regarded as conclusive.

(c) *Variations in the sex ratio*

Of the publications already mentioned, only that of Neel et al.[7] supplies any usable material. For example, neither Murphy & Goldstein,[5] nor Maurer[6] nor Crow[9] indicate the sex of the children; and although Macht & Lawrence[8] give some figures, they do not specify the sex of about 10% of the children, so that one can hardly rely on their statistics.

In their preliminary report, Neel et al.[7] showed that among the offspring of the survivors in Nagasaki there was a statistically significant deviation of the sex ratio, an increase being observed among the children of irradiated fathers and a decrease among those of irradiated mothers. On the other hand, such variations were small or non-existent in the more numerous offspring of the Hiroshima survivors.

At the First International Congress of Human Genetics, held in Copenhagen in August 1956, Dr. J. V. Neel presented some further statistics on the subjects mentioned above, including all the births which had occurred in these families since 1953. In this larger sample, the deviations observed in 1953 are no longer discernible.

In Paris, a survey has been carried out on the offspring of subjects given pelvic radiotherapy in all the hospitals in the city and the surrounding districts (Turpin, Lejeune & Rethore).[8] The initial findings, which are concerned exclusively with the sex ratio, were presented by Professor Turpin at the First International Congress of Human Genetics; they are briefly summarized in the table below.

Offspring of various subjects before and after pelvic radiotherapy

Subjects and reason for treatment	Number of children		Sex ratio
	♂	♀	
Before treatment:			
Men (138); various reasons	116	115	0.502±0.034
Men (284); sciatica	242	223	0.520±0.024
Women (154)	131	106	0.553±0.034
After treatment:			
Men (95); various reasons ($\bar{r}$* = 1461 r)	68	62	0.523±0.048
Men (194); sciatica ($\bar{r}$ = 1295 r)	157	118	0.571±0.030
Women (97); ($\bar{r}$ = 1360 r)	63	73	0.463±0.044

*$\bar{r}$ = average skin dose, *not* gonad dose.

The figures given in the table show that, before treatment, the sex ratio of the children was statistically comparable in the two groups, i. e., the male and female subjects. After treatment of one of the parents, however, the sex ratio increased in the offspring of the treated fathers and decreased in those of the treated mothers, this heterogeneity being statistically significant.

Conclusions

In concluding this very rapid review of the few usable data at present available, the writer would like to stress the following two points:

1. The gonad dose per 30 years, in the form in which it has already been established,[10, 11] probably gives an acceptable approximation of the risk resulting from artificial ionizing radiation. Nevertheless, an accurate evaluation can be arrived at only by systematic recording of all individual exposures. Moreover,

[9] Crow, J. F. (1955), Amer. J. Roentgenol. 73, 467.

[11] United States of America, National Academy of Sciences (1956), Biological effects of atomic radiation.

it is essential that the gonad dose actually received during irradiation under the conditions obtaining in practice should be checked experimentally. The first—and perhaps the most valuable—result of such investigations would probably be a substantial decrease in the degree of exposure of the gonads.

2. From an analysis of the observations already made, it appears that with the doses used in radiotherapy, it would probably be possible to detect some effect in the first generation. The urgency of research in this connection need hardly be stressed. It is only when a list of the mutations which are at present detectable has been drawn up that it will be possible to extrapolate and obtain an estimate of the over-all genetic damage.

Annex 6

Gonad Doses From Diagnostic and Therapeutic Radiology [1]

DIAGNOSTIC RADIOLOGY

Several estimates have been made recently of the gonad dose to the population in excess of that from natural background radiation, resulting from diagnostic radiology. These range in value from approximately 10% of the background radiation (Martin [2]) to approximately 58% (Clark [3]). Intermediate between these two is the estimate of Osborn & Smith [4] of at least 22%. There appears to be some agreement, on present knowledge, that the "doubling dose" for many may lie between 30 and 80 r in a period of 30 years. The concept of the "doubling dose" is, however, an over-simplification of the situation, as there most likely exists a spectrum of gene sensitivity. It may well be that already we are in the position that the mutation rate for some genes is significantly raised.

The most comprehensive analysis yet made of the gonad dose from diagnostic radiology is that of Osborn & Smith.[4] These authors make a number of points of considerable importance. First, they draw attention to the rapid expansion in the use of diagnostic X-ray procedures, adducing evidence that in England and Wales the number of X-ray examinations may, at the present time, be increasing by about 12% per year, and that in 1954 between 17 and 18 million examinations were made. They point out, however, that the adverse effect of this expansion, so far as the gonad dose is concerned, is offset to some extent by technical advances which have reduced the amount of necessary radiation exposure. Secondly, they draw attention to the important fact that only a small number of examinations, amounting to about 7% of the total, contribute the major portion (about 75%) of the gonad dose. These examinations are those of the hips, the lumbo-sacral spine, the pelvis, the urinary tract (intravenous and retrograde pyelography) and pelvimetry. By and large these findings are comparable to those of Martin.[2]

Of serious import is the widespread use of pelvimetry and other X-ray obstetrical examinations of the abdomen, not to speak of examination of the maternal abdomen for other than obstetrical purposes. According to Osborn & Smith, *at least* 26,000 pelvimetries are carried out annually in England and Wales and 86,000 other obstetrical X-ray examinations. These authors calculate that the maternal gonad dose from pelvimetry alone amounts to 3% of the gonad dose to the total population of both sexes, and the foetal dose to as much as 15.6%.

The real criticism of the work of Osborn & Smith lies in the fact that their results are based on a sample of only five hospitals—two teaching and two non-teaching hospitals and one children's hospital. It is doubtful whether this is an adequately representative sample of the hospitals of England and Wales, particularly as there is some evidence, especially from a study of pelvimetry, of considerable variations in radiographic techniques.

THERAPEUTIC RADIOLOGY

The great majority of patients treated in radiotherapy centres are suffering from malignant disease and are either actually or effectively past the reproduc-

tive age. However, a proportion of young persons are treated for a variety of nonmalignant conditions. These conditions are grouped into those treated during childhood and those treated during early adult life. In the former group are haemangiomata, keloids, hypertrophic tonsillar tissue, bone cysts, etc. The conditions treated during early adult life are mainly ankylosing spondylitis, skin diseases, keloids, some menstrual disturbances and, occasionally, bone cysts.

The childhood conditions chiefly occur on the upper half of the trunk and on the limbs, and, on the whole, are treated with low-voltage radiation given on small localized fields. It is unlikely that these treatments contribute to the gonad dose to any great extent.

Of the conditions irradiated in early adult life, so far as experience in Great Britain is concerned, the treatment of ankylosing spondylitis is likely to contribute an appreciable fraction to the gonad dose. Some tentative estimates which have been made of the size of this fraction are given below. No information is available on the contribution from the treatment of skin diseases, but there is every reason for believing that it may also be appreciable.

ANKYLOSING SPONDYLITIS

During the past year an epidemiological survey has been carried out to determine the incidence of leukaemia among patients treated with X-rays for ankylosing spondylitis. This survey covered all the radiotherapy departments of England and Wales, and of Scotland, at present operating under the respective National Health Services. In the course of the survey, data were recorded concerning 13,352 patients, who were treated between the years 1935 and 1954, inclusive—presumably the majority, if not the great majority, of the patients treated for this disease in Great Britain during the period in question.

It is possible to make some rough and very preliminary estimates of the minimum contribution to the gonad dose as the result of the treatment of ankylosing spondylitis in Great Britain, on the assumption that the testes are not shielded during treatment.

The beneficial effects of X-ray treatment for this disease were only widely recognized during the Second World War, and there was a steady annual increase in the number of new patients irradiated up to 1950, since when there has been a tendency for the number to diminish slightly. For the period 1949 to 1954 the average number of new cases per year was 1336, of which 1109 (83%) were males. Of these 53% were under the age of 35. Of the females, 43% were less than 35 years of age.

The average standard first course of treatment for a male patient has been taken as follows (based on dosage information from a random sample of approximately one in six of the whole population):

(a) A single 15 cm x 10 cm posterior field centred over the sacro-iliac joints, the large axis of the field being horizontal.

(b) A series of fields irradiating the whole length of the spine and extending from the upper margin of the sacro-iliac field to the upper part of the neck. On an average, the breadth of these fields is 7.5 cm.

(c) A total skin dose to each field of 1500 r (half value layer 1.6 mm).

From measurements made in a phantom man it appears that a dose of about 45 r is received in the male gonads during such a course of treatment.

Measurements have not been made of the gonad dose received by females. In some centres the female sacro-iliac area was treated similarly to the male area; but in many others definite attempts were made to avoid the ovaries. The direct irradiation of the sacro-iliac region to 1500 r is almost certain to induce permanent sterility. For present purposes it is assumed that the ovarian dose received is on an average 45 r.

The contributions to the gonad doses every year from the treatment of ankylosing spondylitis have been calculated (see table below) on the basis of the following *de facto* populations for England, Wales and Scotland (1952):

	15–34 years	All ages
Males	6.6×10^6	2.37×10^7
Females	6.8×10^6	2.56×10^7
Total	1.34×10^7	4.93×10^7

Gonad dose (in milliroentgens) per head of population per year in England, Wales, and Scotland

	15-34 years	All ages
Males	4.0	2.1
Females	0.6	0.4
Both sexes	2.3	1.2

These estimates can be considered to be minimal ones. No less than 46% of the males and 44% of the females were given more than one course of treatment. Many of these additional courses were given to the lumbo-sacral region and to the hip joints. However, two other factors which tend to diminish either the size or the effectiveness of the gonad dose must be taken into consideration. First in some radiotherapy centres it was standard practice to provide some form of lead shielding for the testes; this was by no means a universal habit, however, and a number of instances of male infertility, some of which could have been the result of X-ray exposure, were discovered. Secondly, it may well be that sufferers from spondylitis are sub-fertile. The disease is a crippling one and is frequently accompanied by pulmonary tuberculosis and ulcerative colitis. There is, however, no published evidence on this point.

To sum up, the radiotherapy of patients suffering from ankylosing spondylitis in Great Britain will give a gonad dose per year of at least 1% of the natural background, and possibly appreciably higher. A more rigorous examination of the contribution from this source, and an analysis of the contribution from other types of radiotherapy, including the use of radioactive isotopes, could well bring the total contribution from radiotherapy up to the level of about 8% suggested by Clark[3] for the USA, or perhaps to an even higher level.

DISCUSSION

So far as the writer is aware there is no direct evidence of a steady upward trend in the incidence of any of the undesirable traits that might be expected with any increase in the mutation rate due to the steady expansion of medical radiology. The direct epidemiological approach to this problem is clearly beset with difficulties, not the least being the very large population that would have to be kept under observation and the inaccuracy and inadequacy of death certification.

There is, however, some evidence from which it could be argued indirectly that an increase in undesirable traits may already be taking place. For example, recent work has demonstrated a significant increase in the mortality from leukaemia among persons treated with X-rays for ankylosing spondylitis, and it has also been possible to demonstrate the existence of a relationship between the annual incidence of leukaemia in these patients and the radiation dose to the bone-marrow. Some preliminary data have been published (Court Brown & Doll[5]). On the evidence as it stands it seems possible that radiation leukaemogenesis in man is a non-threshold effect, and that over the range of dose met with in ordinary civilian life the dose-response relationship is a simple proportional one, analogous to that for the induction of mutations. If this were finally shown to be the case, two deductions would become valid. First, that a proportion of naturally occurring cases of leukaemia are probably due to natural background radiation; and, secondly, that any increase in the background radiation from artificial sources will be associated with an increased mortality from leukaemia.

The mortality from leukaemia is known to be rising. Thus, the annual crude death-rate for both sexes rose in England and Wales from 26 in 1940 to 49 in 1954. The corresponding figures for Denmark are 48 and 71, for Canada 30 and 51, and for the USA 39 and 63 (in 1953). Undoubtedly part of this increase is due to changes in diagnostic criteria and improvements in diagnostic techniques. There is, however, a general feeling that it may in part be real

[5] Court Brown, W. M. & Doll, R. (1956), Appendix B: Leukaemia and aplastic anaemia in patients treated with X-rays for ankylosing spondylitis. In: Great Britain, Medical Research Council, The hazards to man of nuclear and allied radiations, London, p. 87.

and absolute. If this be the case, and if the dose-response relationship over the relevant range of dose be linear, then part of the increased mortality from leukaemia may well be due to the expanding use of radiations, particularly diagnostic radiology. If the incidents of such traits as haemophilia, muscular dystrophy, and achondroplasia could be examined in the same way, it is more than probable that at least a qualitatively similar upward trend would be found.

ANNEX 7

MUTATION IN MAN [1]

1. INTRODUCTION

The study of gene mutation in man has two aspects. The first concerns the ascertainment of spontaneous mutation rates at specified loci. This gives information about human evolution in general as well as about the causation of certain rare diseases and defects. The second aspect, which has only recently become significant, concerns artificially produced mutagens and, in particular, the genetical effects of ionizing radiation. In order to estimate the magnitude of these effects a knowledge of spontaneous mutation rates at given loci is required and the sensitivity of these loci to radiation needs to be ascertained.

2. MEASUREMENT OF SPONTANEOUS MUTATION RATE

Estimation of mutation rate in man, in relation to any given hereditary trait, depends upon ascertaining three things, the incidence of the trait in the general population, the nature of the genetical contribution to the cause of the trait, and the fitness of the genotypes concerned. These phenomena are not necessarily constant. As seen in the population at the present time they may not represent the true picture over a long series of generations, during which natural selection has been acting. They only give us the first clue to conditions which govern genic equilibrium in human populations.

There are two standard methods of approach, the direct and the indirect.

(i) Direct observation

The most favorable case for estimating mutation rate directly occurs when the gene studied is detectable with certainty or regularity in heterozygotes. Instances of fresh mutation can then be observed in families where a gene appears in an offspring although it was not present in the parents. The ideal kind of regular dominance required for this is rarely (perhaps never) found in human genetics. Man is a wild species, under natural selection, unlike laboratory stocks, and consequently most single gene effects, especially those shown in heterozygotes, are subject to modification. Even with the most reliable characters, such as blood group antigens, suppression is possible by gene interaction (Levine et al. 1955); such events could easily be misinterpreted as evidence of mutation by the unwary.

The situation for sex-linked genes is quite favourable, theoretically, for direct observation of fresh mutation because modification of a character shown in homozygous males is usually slight. Occasional families will be observed in which the probability is very great that the disease in the propositus is due to fresh mutation. The proportion of sporadic cases can also be inferred if the sibships show an excess of sporadic propositi.

For recessive traits the problem is much more difficult because heterozygous carriers are not detectable in ordinary circumstances. In cases where special techniques have been developed for identification of carriers the problem is resolved into one of detection of mutation for a dominant condition, as demonstrated by Vanderpitts et al. (1955) for sickle cell trait. Direct observation of cases of recessive diseases due to fresh mutation is very unlikely to be possible because only a very small proportion of cases of a recessive trait in a given generation can be attributed to fresh mutation in a parent. For diseases in which a single gene is only a part cause and in which environment has a great effect upon manifestation, the contribution of spontaneous mutation is likely to be even less significant. The same applies to conditions due to the interaction of many genes. For none of them can mutation rates be directly determined.

---

[1] Submitted by Dr. L. S. Penrose, Galton Professor of Eugenics, University College, London, England.

(ii) The indirect argument

When the total effects of a gene are very disadvantageous an indirect line of argument can be used for estimating mutation rate, even though the gene may not be manifest in the heterozygous state. Principles on which the indirect estimation of mutation rates can be based were laid down by Haldane (1932). The assumption can be made that the human population is in a state approaching genetical equilibrium under natural selection. It is supposed that disadvantageous genes could not persist in the population unless their extinction by selective mortality were completely balanced by the resurrence of mutation.

In the case of dominant or sex-linked characters associated with very high mortality, the direct measurement of mutation rate can be supplemented, and its plausibility greatly strengthened, by the indirect argument. The best situation for this combination occurs in the case of a very deleterious dominant trait. This is a rare circumstance. If the disease is not very lethal, there will be difficulty in measuring the unfitness conferred by the gene: if it is very lethal, there is difficulty in providing the dominant mode of inheritance, as it will seldom last even for two generations. Sometimes the problem might be solved for a locus, which had several different known alleles, some producing milder and others severer types of disease. Then, in each of the severest cases, mutation of a lethal allele will be observable. This possibly occurs in both epiloia and chondrodystrophy. For mild alleles, which last for several generations, the proportion of cases due to fresh mutation is correspondingly smaller.

Estimates which are entirely indirect, are untrustworthy but they have actually been made for a variety of genes recognized only by their recessive effects. One cause of uncertainty with recessive traits is that allowance has to be made for the results of inbreeding. Another likely source of error is that genetical equilibrium can be maintained not only by mutation but also by slightly advantageous effects in heterozygotes. That is to say, on the balance, the total effect of a gene may be much less bad than appears from studying abnormal homozygotes and then an indirect estimate of mutation rate will give much too high a value.

3. SOME STANDARD ESTIMATES OF HUMAN MUTATION RATES

Mutation rates have been calculated for quite a large number of genes in man. It is preferable to express them in terms of loci per generation, if we wish to avoid controversy, because slightly different forms of the diseases concerned can be accounted for by the same allele or by different alleles. If there are several very closely linked loci giving rise to a pseudoallelic system, the real mutation rate for each separate element is lowered by a factor depending upon the number of elements in the complex.

(i) Dominants

The most exact estimates for supposedly single loci are probably those for very deleterious dominant traits (see Table 1). Allowing for the probability that more than one disease entity may be classified under each heading, they are maximal values. The average value for six conditions is about 14×10^{-6}.

Owing to the classification of more than one type of chondrodystrophy under the same heading the rate given is likely to be considerably too high. According to Grebe (1955) there are several clinical types; and some cases may be due to recessive genes. Furthermore, these different types may have different mutation rates.

Another, dominant, condition, which apparently has a relatively high mutation rate, namely, retinoblastoma, occurs perhaps not infrequently as a phenocopy (Vogel 1954) not transmissible to the next generation. The same idea could be applied also to other conditions listed in Table 1, such as microphthalmos.

The indirect argument, which supports all these estimations, can only be used when there is a strong selection against the gene studied. Theoretically it should be possible to obtain mutation figures for several blood antigens, e. g. *ABO* or *MNS*, but selection against any of these genes is too slight and indefinite to be used as indirect support for the mutation hypothesis. On the other hand, the indirect argument can be extended to cover certain cases in which the combination of several genes at different loci is lethal or very deleterious. Thus a lethal condition, caused by the simultaneous presence of two heterozygous genes, will imply that each of the genes concerned mutates frequently enough

to make good the loss occasioned when it occurs in conjunction with the other.

Taking all these considerations together we can reasonably assume that the mutation rates for loci giving rise to dominant genes, though somewhat too high, are of the right order of magnitude. It seems that, for most of these dominant diseases, the rate should be considered to be about 5×10^{-6}.

(*ii*) *Sex-linked loci*

The prevalence in man of sex-linked diseases which are very lethal is difficult to explain except on a mutation hypothesis. Direct evidence based upon observed low incidence of haemophilia in sibships and in maternal collateral relative also supports this explanation. The matter has been repeatedly investigated by Haldane (1946, 1955) and there seems to be some evidence that mutation more commonly occurs in males than in females. The two sex-linked diseases which have given information about human mutation rate are haemophilia and pseudohypertrophic muscular dystrophy. In both cases there are many types of illness easily confused with one another clinically. Sex-linked types are identified by pedigree studies and by their occurrence in males only but, by this process, some autosomal cases may occasionally be incorrectly included. A characteristic difficulty is the exclusion of autosomal sex-limited conditions.

In the standard examples of haemophilia and sex-linked muscular dystrophy, mutation rates have been estimated several times but always on the assumption that, in each disease, there is only one locus involved. These rates, as shown in Table 1, are considerably higher than the direct estimates for autosomal dominants. Perhaps the X-chromosome is peculiar in that it has many complex loci or distinct loci with similar effects.

(*iii*) *Recessive traits*

A recessive trait in man can be defined as one which depends upon a gene in homozygous form. There may be mild manifestations detectable in heterozygotes (e. g. thalassaemia, galactosaemia, cystinuria) but the disease in the homozygote is the effect with which we are concerned. The indirect estimates of mutation rates for recessive diseases, shown in Table 2, assume that the heterozygote is neutral in its effect upon fitness. If the heterozygotes were deleterious, as suggested by Böök (1953) for schizophrenia, the values would have to be increased. Conversely if heterozygotes were slightly favourable, the values would have to be reduced.

TABLE 1.—*Estimates of spontaneous mutation rates of some human genes: (a) Dominant inheritance; (b) sex-linked inheritance*

[1] See Penrose (1956a).

A very slight amount of heterozygous advantage is sufficient to keep a rare recessive lethal in stable genic equilibrium in the absence of mutation so that the calculation of mutation rate is very easily invalidated. This is an extremely important principle and is worthy of detailed consideration.

Most well known recessive traits cannot easily be supposed to have arrived at their existing levels of gene frequency (e. g. 1/100 for phenylketonuria) by chance or by "drift". The situation for commoner genes is even more striking. For tnalassaemia and sickle cell trait (Neel 1951), cystic fibrosis (Goodman & Reed 1952), spastic diplegia (Böök 1953) and schizophrenia (Penrose 1956a) improbably high mutation rates have to be postulated. Indeed the maximum rate for sickle cell trait, derived from direct observation on heterozygotes, is much lower than that calculated indirectly (Vanderpitte et al. 1955). These common traits could not have easily established themselves unless the heterozygotes had some advantage. The advantages may have been local ones in the distant past, for example, ability to withstand infections, plagues, famines, abnormal climates and so on.

It is not necessary to postulate any virtue in the heterozygote as such. It could be sufficient if the mutant alleles were favourable at one epoch and unfavourable at another epoch, in different circumstances or at different stages of the same life cycle. The principle of genetical stability produced by heterozygous advantage or, more accurately, homozygous disadvantage, is one which has been understood for a long time (Fisher 1930) but only recently taken seriously. In human genetics it is exhibited by such a system as may be present in relation to the sickle cell trait in Africans. The disadvantage of one homozygote, SS, which suffers from anaemia, is balanced to some extent by disadvantage of the homozygote, *AA*, which is especially susceptible to malaria caused by *P. Falciparum.* Balanced human genetical systems are shown in metrical traits because the extreme types, which tend to be homozygous, are relatively unfavourable. Examples are stature, birth weight and intelligence level. For intelligence, in particular, there is a marked fertility differential in one direction and a viability differential in the other. That is, low intelligence levels are associated with low viability and high levels with low fertility.

In all such cases of balanced polymorphism the variation, which is apparently, reduced each generation by loss of extreme types, is not maintained by fresh mutation. It is maintained simply because the heterozygotes, who tend to have medium metrical value, are the parents of most children in each successive generation. In these circumstances it is quite useless to attempt to estimate the mutation rates of component genes: any indirect estimate will be far too high.

It has been suggested by Haldane (1939) that the converse may be true, namely that mutation rate estimates for recessive traits are often too low. The argument used is that the true incidence, which recurrent mutation would theoretically balance, has in the past been much greater than it is at the present time. This is likely because inbreeding, which facilitates the appearance of recessive

diseases, has been gradually diminishing for many decades in all civilized communities. I believe this argument to be unsound because the incidence of rare recessive traits in man is extremely irregularly distributed. Tay-Sachs disease is almost confined to Jewish communities as also is pentosuria, Cooley's disease has centre in the Po delta. Phenylketonuria, on the other hand, does not occur among Jews. Sickle cell anaemia is common in Africans. Juvenile amauratic idiocy is commonest in Sweden and acatalazaemia has only been found in Japan. These facts suggest that recessive mutations are very rare but that occasionally they have spread for unknown reasons probably connected with heterozygous advantage at one epoch or another. If mutations were not very rare the same set of recessive diseases would appear in all communities or at least in all inbred communities throughout the world.

To sum up the discussion on spontaneous mutation rate, my view is that, for a variety of reasons, most mutation rates already calculated are too high; points to be stressed are, first, that mutation may be mimicked by suppression of even the most regular kinds of dominant inheritance, secondly that different conditions are grouped under single clinical headings, and, thirdly, that heterozygotes of established recessive lethal traits are likely to have carried slight advantages in the past even if they do not at the present time.

4. EFFECT OF INDUCED MUTATIONS

The immediate effect of an increase above spontaneous mutation rate is most easily calculated when the gene is dominant. The rule, however, is quite general. The increase of incidence of any trait in the first generation, due to induced mutation, depends upon the proportion of cases due to fresh mutation in ordinary circumstances. For lethal dominants and sex-linked traits this proportion is large but in lethal recessives it is very small. It is also small for dominants which are very imperfectly manifested as with those contributing to multifactorial traits. The rule refers to the effect in the first generation or in closely succeeding generations, which especially interest people now living. The total quantitative effect on the population of altered mutation rate is theoretically the same whatever the manner of inheritance but, in the case of recessive or heavily modified dominants, a slight effect is maintained over such an enormous length of time, many thousands of years.

The proportion of cases of a lethal condition due to fresh mutation in any given generation can be estimated on the basis of the indirect argument. If the mutation rate, μ, is expressed as a function of the gene frequency thus,

$$\mu=f(q)$$

it follows formally that the proportion of cases in any given generation due to fresh mutation, a quantity which can be called M, is given by the approximation,

$$M=d\mu/dq.$$

For example, for a recessive lethal trait,

$$\mu=q^2, \text{ and so } M=2q.$$

Substituting 1/40 000 for q^2, the frequency of juvenile amaurotic idiocy as estimated by Sjörgren (1931), we get M=1/100. In view of what has been said about the use of the indirect method this is probably an upper limit but it shows how little effect a change in spontaneous mutation rate would have upon the incidence in the next generation after it had occurred or, indeed, in any subsequent generation. Doubling the mutation rate would only increase the incidence by one or two per cent. in the first subsequent generation.

5. SENSITIVITY OF HUMAN LOCI TO RADIATION

Much has been written about the probable sensitivity of human loci to radiation using experimental data on lower animals as a basis for comparison. Direct observations on man, however, are essential and three sources of information are at present available.

(i) *The comparison of offspring of selected parents exposed to different quantities of radiation*

This is the method attempted in several comparative studies. Children of radiologists have been examined by Crow (1955) and also by Macht & Lawrence

(1955) and the exposed Japanese population by Neel and his colleagues (Neel & Schull 1954). A development of the same idea is implied in two other proposed types of investigation. One of these is the special examination of children of patients who have received large therapeutic doses of radiation before conception, as may be the case in sufferers from spondylitis. The other suggested method is to examine the incidence of mutations in areas where the natural background radiation is high. Each of these methods, though theoretically possible, has its own special technical difficulties. There is a general objection to all of them, however. Fresh mutation is a phenomenon which can only very rarely be observed even though it may be occurring all the time. To search for slight increases in incidence of traits which, in the case of known recessives, will not exceed one per cent. requires the collection of enormous quantities of data and results are likely to be inconclusive. These methods are, in fact, rather inefficient even after allowances have been made for sources of error peculiar to each type of enquiry.

(ii) The examination of parental history in known instances of mutation

An alternative and more efficient method, which has received scant attention hitherto, is the careful examination of the personal histories of parents and, in certain instances, of grandparents, for groups of cases where fresh mutation is suspected of having played a part in causing disease in the offspring. This method has already produced valuable results by using the simple test of parental age.

Clearly, the older the parent the more likely he is to have been subjected to mutagenic influences. If the influence is background radiation, at the age of 40 the dose will have been twice that received at the age of 20. The net effect on parental age distribution of diseases in the offspring caused by background radiation alone, though definite, would be slight. The expected average increase would be scarcely more than one year above normal parental age (Penrose 1955a). Marked effects confined to one or other parent have, however, been observed in several malformations. Marked increase of father's age has been found in chondrodystrophy and acrocephalosyndactyly, as shown in Table 3. On the other hand, the incidence of mongolism is associated solely with advancing age of the mother. It would appear, thus, that, in so far as these traits may have their origin in fresh mutations, the causes must be different. In particular, a marked increase in paternal age strongly suggests some process connected with cell division in the spermatogonial stage which might be chemical in origin. The effect does not appear in other traits thought to be often caused by fresh mutation, such as epiloia, neurofibromatosis and retinoblastoma, where only slight and statistically insignificant parental age increases have been registered. Mongolism would, by the same test, appear to have an entirely different cause.

TABLE 3.—*Mean parental ages in sporadic cases of diseases attributed to fresh mutation compared with control mean ages*

Disease	Source [1]	Control mean [2]	Number of cases	Excess over control mean (years)	
				Father's mean age	Mother's mean age
Chondrodystrophy	Mørch (1942)	D	97	+5.4	+3.5
	Krooth (1952)	E	16 } 176	+6.8 } +5.1	+5.7 } +3.6
	Grebe (1955)	G	63	+4.3	+3.1
Acrocephalosyndactyly	Grebe (1944)	G	7	+5.5	+3.5
Epiloia	Gunther & Penrose (1935)	E	12 } 33	+0.8 } +0.5	+0.3 } +0.4
	Borberg (1951)	D	21	+0.4	+0.5
Neurofibromatosis	Borberg (1951)	D	49	+0.9	+0.8
Retinoblastoma	Neel & Falls (1954)	M	64	+0.5	+0.7
Mongolism	Schulz (1931)	G	80	+5.3	+7.7
	Øster (1953)	D	369 } 664	+5.3 } +5.8	+6.5 } +6.9
	Penrose (1955)	E	215	+6.8	+7.4

[1] See Penrose (1956b).
[2] E, England: father 30.9; mother 28.6. D, Denmark: father 33.3; mother 28.6. G, Germany: father 32.6; mother 28.9. M, Michigan, USA: father 30.5; mother 26.4.

The investigation of parental age is only one part of the problem. The history of parental exposure to X-rays and other kinds of radiation needs to be recorded;

occupational risks and possible exposure to chemical mutagens from external sources could also be made the subject of enquiry.

(*iii*) *Observations on somatic cells*

It has been suggested that a tissue culture treated by exposure to a known dose of radiation could serve to investigate the sensitivity of human cells. Techniques of this purpose will no doubt be developed in time though such experiments may never be critical because germ cells could have different sensitivity from that of somatic cells. This objection may be for the moment left on one side, however, while we search for existing data which might give clues to mutation rate in somatic cells. The obvious source of information is observations concerning inductions of tumours by radiation.

It has until recently usually been assumed that very small amounts of ionizing radiation have no effect on the induction of leukaemia. This is now doubted and the relation between bone marrow dose and incidence of leukaemia is thought to be not unlike the linear effect observed in the induction of X-chromosome lethals in *Drosophila*. Some idea of the dosage to bone marrow required to double the spontaneous leukaemia rate can be obtained from unpublished figures (Court, Brown & Doll 1956) and it is in the region of 30 to 50 roentgen units.

This line of thought leads to another interesting idea. The suggestion has been made that many sporadic cases of retinoblastoma arise as phenocopies. Is it not possible that these phenocopies are simply somatic mutations of the same gene which sometimes is carried in the germ track causing a dominant type of inheritance?

6. THE "LOAD" OF ABNORMAL GENES IN MAN

Finally, I would like to mention one or two points about the total effect of mutation on man since this has been so much discussed recently. Consider the total number of zygotes formed in a generation. We have no idea how many fail to pass through the first few divisions and never develop into embryos. Indeed it is impossible to estimate how many embryos are lost in the first six weeks after fertilization. According to Yerushalmy (1945) 15 per cent. of human pregnancies are known to terminate in miscarriages or abortions. Beyond this, three per cent. are stillborn and two per cent. are neonatal deaths. In addition, early mortality after the first month amounts to three per cent. These are figures for European and North American communities, where infectious diseases and malnutrition are under efficient control. In many parts of the world they would be gross underestimates. Among those who survive to adult status, 20 per cent. are unmarried and of those who do marry some 10 per cent. are infertile. How much of this continuous loss of zygotes, which may amount to about 50 per cent., is genetic is not known; by analogy with results obtained on ordinary metrical traits such as stature and intelligence, about half of this loss of zygotes might me directly hereditary. Perhaps the main factors are recessive lethals. If this were so, the indirect argument would lead to the conclusion that about a quarter of zygotes are lost each generation and that the genes which are thereby eliminated are replaced by fresh mutations. This points to the further conclusion, that a large increase in mutation rate, say permanent doubling, would eventually increase this lethal lead to a half and would greatly reduce human fitness, though the immediate effects would be small. However, for reasons given earlier, I do not suppose this picture to be an accurate one. Much of the permanent lethality which we experience is likely to be due to balanced genetical mechanism which do not require the assumption of appreciable amounts of mutation to maintain them. As I have previously pointed out (Penrose 1955b) improved living conditions are likely to reduce the frequencies of recessive genes whose prevalence is due to heterozygous advantage. Thus genetic damage which may be done by increase of mutation rate, due to industrial and medical uses of radiation, may be offset in the future by the improvements in hygiene which are taking place at the present time all over the world.

Possible Areas With Sufficiently Different Background-Radiation Levels To Permit Detection of Differences in Mutation Rates of "Marker" Genes [1]

The impressive developments in atomic research in recent years and the increasing application of nuclear energy in many fields of human endeavour have brought to the forefront serious problems concerning the long-term effects of radiation on man and his environment. In order to obtain a better appreciation of the totality of effects on human populations, it is necessary first to take into account the magnitude of the various components of natural background radiation as well as the radioactive elements normally present in the body and environment. The magnitude of the contributions of cosmic rays, radioactive radiations from the earth's surface and radioactive elements in the body is shown in Table I.

In his paper (see p. 1761), Professor R. M. Sievert has dealt with the naturally occurring sources of radiation and measurements of low-level radioactivity. No attempt will therefore be made here to traverse this ground again.

MONAZITE AREAS

In this paper, the writer will endeavour to show that conditions in certain parts of India are particularly favourable for studies of the differences in muta-

[1] Submitted by Dr. A. R. Gopal-Ayengar, Head, Biology Division, Department of Atomic Energy, Indian Cancer Research Centre, Bombay, India.

tion rates due to differences in background radiation. But before doing so, it may perhaps not be out of place to say a few words about thorium ores and monazite, since it is these constituents on the earth's surface that contribute to the buildup of natural background levels in certain areas.

Like uranium, thorium is a derivative of acid rocks and is for the most part concentrated in granites, syenites and their corresponding pegmatites. There is, however, a basic geochemical difference between the two radioactive elements, in that while the weathering of thorium ores supervenes by and large a process of physical comminution, that of uranium ores is acted upon by chemical processes. In consequence, thorium becomes incorporated into sediments as discrete, detrital grains of primary mineral, whereas secondary uranium in sedimentary formation occurs as a diffuse, chemically absorbed entity on carbonaceous matter, phosphates and clays. The usual ore minerals of thorium are monazite, thorite and thorianite. Of these, mention will be made only of monazite, the principal ore.

Without entering into any detailed description of the mode of formation of monazite or the manner in which it finds its way into the sea—aspects which legitimately belong to the province of geology—the writer will pass on to the stage where it is found to accumulate as beach-sand deposits in different parts of the world.

As to geographical areas, menazite deposits have been found admixed with ilmenite, rutile, zircon and other rare-earth elements in patches along the coastline of India. The monazite has accumulated along the sea-shores by a process of natural concentration out of the products of rock decay in the course of long geological ages. The heaviest deposits occur in Travancore-Cochin State, in the south-west part of India. Here, over a stretch of about 100 miles (160 km), the coastline is characterized by patches of this radioactive sand. The most concentrated distribution is to be found over a 12-mile range from Neendakara to Kayankulam and in another stretch, a mile long, at Manavala-Kurichi. Although the monazite constitutes only 1% of the beach sand, the thorium content in it is one of the highest in the world, amounting to about 10.5%. Small pockets of the littoral belt also contain even higher amounts (33%).

Other areas of the world worth mentioning in this context are: Brazil, Ceylon, Indonesia, Australia, the Belgian Congo, parts of the USSR, South Africa, Madagascar, Korea, Spain and the USA. According to Davidson,[8] the beach-sand deposits of Brazil are situated in the States of Rio de Janeiro, Espirito Santo, Bahia, Parahyba and Rio Grande do Norte, extending along a coastline of more than 1000 miles, the largest accumulation being at Comaxatiba and Guaratiba in Bahia, Guarapary in Espirito Santo, Barra do Itabopoana in Rio de Janeiro and the so-called "fossil bar". Although the ratio of monazite to the other minerals is higher than in the Indian and most other sands, the Brazilian concentrate apparently has only 5–6% of thoria, as compared with 10% in Travancore.

MEASUREMENT

A preliminary sample survey of the monazite areas of Travancore-Cochin was carried out recently by the Health Physics and Air Monitoring Divisions of the Department of Atomic Energy, Government of India, to estimate the internal and external radiation exposures of the population living in the coastal areas. A more extended series of measurements is under way to obtain detailed information on the levels of activity in the areas of highest background radiation, where there is also a high population density. Measurements have also been taken in and around the houses at the active area.

The external radiation exposure in the region is caused by:

(a) β–γ radiation from natural uranium and thorium contained in the monazite, and

(b) β–γ radiation from radon, thoron and their decay products in the air (Table II).

The external exposure to alpha radiation is not important because of the small range of the particles.

Measurements were made with a thin window β–γ, Geiger-Müller counter with a thickness of 20–30 mg/cm.^{2}. The measuring instrument was calibrated with a thin walled ionization chamber. Measurements of this nature have also been carried out in Sweden by Professor Sievert who, as we have seen has been interested mainly in the measurement of low levels of activity, particularly

[8] Davidson, C. F. (1956) Mining Mag. 94, 197.

the γ radiation from living subjects. On the basis of his painstaking studies he has built up what is probably the most complete body of knowledge obtained so far on radiation exposure in human material of all age groups.

The internal exposure to the population on the monazite sands is caused by the intake of radioactive substances through air, water and food. Moreover, radon and thoron emanating from monazite will add to the contamination of the air in the vicinity. However, these gases decay in the air, and their decay products get attached to fine dust particles in the air from whence they settle down on the soil or on the population. When the air is breathed, a considerable portion of the active dust is retained in the respiratory system, where it undoubtedly acts on the epithelium. The intake of soluble compounds of uranium and thorium through food and water would increase the body burden of uranium and thorium through ingestion and become a permanent source of internal irradiation. The accompanying schematic diagram gives an idea of the disintegration of thorium and its decay products.

Representative series of measurements taken on the beach, at the surface and in the air, as well as those in the houses, are given in Tables III to VI. These relate to Neendakara Chavara (Table III), Shakthikulangara (Table IV), Panderathuruthu (Table V) and parts of Midalum (Table VI).

It will be seen that there is considerable variation in the intensities of the radiation at different points in the measured areas. While the actual amount of radiation that the population receives must remain speculative to a certain extent at this stage, the balance of evidence seems to point to the fact that the population is subjected to fairly high doses. The estimated values in terms of γ doses for different regions range from 200 mr/yr to about 2.6 r/yr. It is further estimated that the population would be exposed to a total γ dose of about 10.20 r over a reproductive span of 30 years. It may be mentioned in this connection that Travancore State has the highest density of population in India; the estimated number of inhabitants in the monazite area is of the order of 100,000. It should be stressed that the total β–γ dose in all cases was 3.5 times higher than that due to γ alone. Although in normal circumstances the β dose could be considered to have a negligible effect, the fact that the decay products of thorium, mesothorium 2 (2.1 Me.) and thorium C (2.25 Me.) are high β-energy emitters should not be lost sight of, especially when it is considered that the people come into close contact with the surface of the soil every time they sit or sleep on it. A correction factor would therefore have to be applied to the γ doses in order to estimate the total dose to the hole body as well as to the gonads.

POSSIBILITIES OF DETECTING DIFFERENCES IN SPONTANEOUS MUTATION RATES

It has become all too clear that the compilation of exact genetical data of man is beset with numerous difficulties: for one thing, there are no pure strains to work with; for another, the generation times are inordinately long. There is also the probability that many the radiation-induced genetic changes would be lethal. A considerable number of recessive mutations are passed through successive generations and may express themselves as physiological aberrations that weaken but do not necessarily kill the individual. In such cases, distinction from incidental disease processes may be difficult if not impossible, and may therefore never be resolved. Many mutations induced by radiation may be expected to affect the fertilized ovum, and hence abortions, foetal deaths, stillbirths, infant mortality, malformations, sex ratios, viability and fertility, etc., are the genetic changes most readily seen and analysed statistically. But what we need to look into also are the possibilities of detecting differences in the mutation rates of "marker" genes of populations exposed to radiation of the order present in the monazite area of Travancore. A careful study of the population structure in this area should furnish information concerning gene frequencies and their distribution in time and space, as well as data on mutation rates. Several years ago, Muller[8] raised the question of the possibility that genic erosion will result in a piling up of deleterious mutations following ameliorative medical practices. Now, in the monazite belt of Travancore we have an almost unique situation, where there would appear to be no relaxation of the forces of selection on the population, since the alleviating action of modern medical services has not found its expression to any appreciable degree. The

[8] Muller, H. J. (1950) Amer. J. hum. Genet. 2, 111.

population has been more or less stationary for generations and might be expected to show differences in mutation rates for particular traits—autosomal dominants or sex-linked recessives of the type already discussed by Professor Stevenson in his paper (see page 5 Annex 9). A control population of comparable dimensions, with similar demographic conditions and normal background radiation exists in the nearby areas.

An inquiry of such a nature would obviously be a long-range one, but would be well worth doing in view of the possibility of thus obtaining some direct evidence on the genetic consequences of naturally occurring high background radiation. The investigation would also be likely to shed light on the dosage relationships for doubling the spontaneous mutation rate and other cognate problems. Moreover, it might also reveal interesting somatic effects, such as the incidence of leukaemia, cancer and other conditions.

TABLE I.—*Level of exposure of human body to background radiation*

[Dose Unit: Milliroentgens per year]

I. RADIOACTIVE ELEMENTS IN THE BODY

Radioactive carbon (15 disintegrations per minute per gram of carbon)	2

Comparisons of Mutation Rates at Single Loci in Man [1]

This note is concerned with the practical problems that arise in attempting to compare phenotype frequency, gene frequency and mutation rates between different communities. Such a comparison may be desirable for a number of reasons and, indeed, it is always something which is inherently of great interest in human population genetics. In one context, however, the comparisons which have been suggested as particularly desirable are those between communities known to have been exposed to widely different total radiation.

It seems most unlikely that it *would* be feasible to detect differences of the small order of magnitude which would be expected in such communities, or if they were detected, to attribute them with confidence to differences in background radiation alone. It would appear necessary to elaborate these and other points of criticism, however, because the suggestion has been made so frequently that it is perhaps better not to ignore, but rather to analyse, the difficulties inherent in such comparisons. This must be the writer's excuse if what follows appears largely destructive.

OUTLINE OF PROBLEMS INVOLVED

The difficulties may be summarized as follows:

1. There are the statis tical problems inherent in attempting to detect small differences in very low frequencies based on small numbers, such as mutation rates in man. Suppose in two populations of about 3,000,000 each it was desired to compare the frequency of a dominant or a sex-linked trait with an approximate expected frequency of 1/30,000. Suppose, also, that a background radiation of 3 r per generation to the gonads was expected to cause 10% of all mutations. If the two areas compared had a difference of 4 r in radiation exposure, then it would be necessary to interpret a difference of some 10–20 in the number of affected individuals in the two populations.

2. There are the hazards of assuming that any differences detected in mutation rates between two areas are, in fact, caused by different exposure to radiation. The proportion of mutations attributable to radiation is not known, and there are other factors—racial, dietary and demographic—each of which separately may determine more variation in rates than that determined by background radiation. The evidence of a close relationship between mutation and parental age is very strong for several of the genes whose expression would be suitable for comparative purposes, so that conventions of age at marriage and of the age interval between the men and women might well greatly influence the mutation rates. There are used in medicine and industry naturally occurring and synthetic substances known to be mutagenic in some lower organisms. Their effects on mammals are unknown.

3. In calculating mutation rates by the indirect method the value adopted for relative fertility of the specific phenotype could be rather critical. Yet in different populations the actual fertility of the phenotype may vary for social reasons, and because of inadequate or differing sources of demographic information it might be that only a very unsatisfactory method could be used in the comparison of two communities. For example in Denmark (Mørch [2]) a high proportion of adult achondroplastics have had offspring, while in Northern Ireland at present only one living achondroplastic is known to have had children (Stevenson [3]). In the State of Michigan, USA, the numbers of offspring born to people of both sexes at different ages can be compared (Falls & Neel [4]) whereas in England and Wales this information is available in respect of females only, and in Northern Ireland there are no national statistics of this kind. Hence the available background demographic information may not be comparable in areas otherwise suitable.

4. An essential for adequate comparison of mutation rates in two communities is that the complete patterns—not the truncated patterns which result from different degrees of ascertainment—should be available. With the best will in the world it is impossible to arrive at complete ascertainment unless the medical services are reasonably well organized, records are good and available, and

---

[4] Falls, H. F., and Neel, J. V. (1951) Arch. Opthal. (Chicago), *46*, 367.

co-operation is readily given by medical and other authorities To take a specific example, it is extremely difficult to find the older surviving sporadic boys with Duchenne-type sex-linked muscular dystrophy. If they have not had medical attention for many years, if they only attended a long time previously a hospital which kept poor records, or if they live in an area where the education authorities tend to ignore children who do not attend school, they may be well nigh impossible to find. Any comparisons between communities would therefore need to be supervised by physicians or other persons with plenty of practical experience of the difficulties and of the devices for checking and cross-checking the efficiency of ascertainment.

5. Lastly, there are the dual problems of diagnosis and of the complications introduced when it is appreciated how diverse the apparently simple relationship between gene and trait usually is. As might be expected from animal work, experience is constantly showing that human syndromes can be determined by genes at various loci or by different alleles. In addition there is, of course, the complication of the occurrence of phenocopies. The more carefully single-gene traits in man are studied, the more complex the picture becomes, so that there is hardly a trait known where there is not either some evidenec or a suspicion that the trait may be determined by various mechanisms. This does not by any means depend only on the text-book descriptions of many traits described as being caused sometimes by dominant, sometimes by recessive and sometimes by sex-linked genes. Many of these may well have arisen from the misinterpretation of pedigrees or from the selective publication of the data of remarkable families. However, clinical and biochemical separation of traits and the increasing practice of studying all families with affected members in a community constantly seem to suggest such probabilities. Perhaps more will come to light when more data are available for the analysis of various measurable characteristics of traits, such as measurements between sibs and between all the phenotypes. Perhaps, too, we shall get help in the future from some further knowledge of the morbid anatomy and histology of genetical conditions. The most remarkable example of all is probably hereditary deaf-mutism, where the evidence is strong that many recessive genes and a few dominant ones can each determine deafness which cannot be separated clinically. It is interesting to see that in mice, where similar evidence is available, even histology fails to reveal differences in lesions produced by different genes In deaf-mutism, too, the so-called "congenital" cases or phenocopies seem to constitute as many as one-third of all cases (Stevenson & Cheeseman [5]).

Such reflections make it difficult to suggest which traits would be suitable for use as markers for comparisons of the kind suggested, and indeed they leave a nasty suspicion in one's mind that certain traits might be chosen as satisfactory largely because not enough is know about them.

TYPES OF TRAIT SUITABLE FOR USE AS MARKERS

It seems worth while here to review briefly the kinds of trait which might be used as markers for mutation rates at specific loci and to point out the practical problems just mentioned as they arise. It will be generally accepted that autosomal-recessive gene traits are quite unsuitable for the purpose. In the first place, they are individually rare. Secondly, variations in inbreeding ratios, difficult to detect except in the crudest form of full-cousin rates in man, together with the fact that if small isolates with close inbreeding produce a number of cases of a rare trait the total rate will be very markedly affected, render it very hazardous to estimate a gene frequency as a preliminary to calculating a mutation rate.

In contrast, autosomal-dominant and sex-linked gene traits offer some opportunities for direct estimations and, being less dependent on vagaries from random mating, offer the chance of indirect calculation of mutation rates based on the theoretical distribution of genotypes at equilibrium developed by Haldane.[6]

It may be presumed with some confidence that the genes for which mutation rates have already been estimated are those whose characteristics are most likely to be suitable for comparative purposes. As will be seen from Tables I and II in which mutation rates for some dominant and sex-linked gene traits are given, the number of adequate calculations made is unfortunately very small and the

[5] Stevenson, A. C., and Cheeseman, E. A. 1956) Ann hum. Genet. *20,* 177.
[6] Haldane, J. B. S. (1935) J. Genet. *31,* 317.

data from which they are derived are frequently rather meagre or dependent on indirect estimates rather than on actual counts. This is intended not so much as a criticism as an indication of the difficulty—and, at times, impossibility—of assembling data which are sufficient in quantity and quality.

AUTOSOMAL DOMINANT GENES

Autosomal dominant genes would seem to offer the best opportunity for collecting data for comparative purposes, and the ideal trait would be one with the following charatceristics:

(b) that only one gene can determine the trait;
phthaimus, heart defect and rudimentary tail, and two had cleft palate, poly-
errors in estimating gene frequency and in identifying new mutant phenotypes);

(c) that the phenotype cannot be mimicked by a phenocopy;

(d) that the condition is recognizable at birth or in early life but that its possessors do not die too young (this is important, in that otherwise defferential mortality experience makes estimates of frequency difficult);

(e) that the frequency of the condition is reasonably high (the lower the frequency, the larger the population which will be needed to detect differences in frequency and, hence, mutation rates):

(f) that selection against the phenotype is marked. (If it is not, direct estimates of mutation rates would be well nigh impossible to obtain as new mutant phenotypes would very seldom be observed. Indirect estimates of the mutation rate would also be less reliable, as unless the dimunition of the effective fertility is big enough to be recognized and measured, such estimates could not be made. In a low frequency trait, with little negative selection, a small number of mutations a few generations previously could result in great differences in phenotype frequency.)

Looking at the traits in Table I and the mutation rates calculated, it is unfortunately easy to point out the deficiencies of each for comparative purposes. Perhaps it may be worth just mentioning them for the benefit of non-medical readers, who may not be familiar with the clinical aspects.

Achondroplasia

There are three certain objections, and another possible one, to the use of achondroplasia as a marker. In the first place, it is fairly clear that achondroplasia as commonly recognized at birth as "different" from achondroplasia as commonly seen in older subject. Pooling the obstetric history and the foetal condition of Mørch's eight and the writer's nine cases of achondroplasia recognized at birth and born to normal parents (Stevenson, 1956), it appears that of the seventeen (six males and eleven females), six were stillborn; eight died shortly after birth; one lived for one year and died of pneumonia; one lived for eighteen months, but never walked or had any teeth, and died of pneumonia; and one lived to twenty-nine years of age. In this last case (one of Mørch's), however, the condition of the father was not known.

Further in this combined series of cases, six of the mothers had hydramnios in pregnancy and three of the babies had other gross anomalies: one had micro-
(a) 100% manifestation in the appropriate genotype (this would obviate
dactyly and syndactyly.

In Northern Ireland a complete ascertainment has been made of 37 subjects presumed to have received fresh mutations, only three of whom were recognized at birth. All this suggests that the cases recognized in hospital at birth have the type of maternal history and foetal appearance which we usually associate with congenital, but not necessarily hereditary, anomalies. It further raises the question whether the possible survival of mild cases of this type may not complicate the gene frequency and fertility issues in the living. It may also be noted here that it would be hazardous to compare the incidence of this condition in births in various hospitals, as the amount and quality of ante-natal care may alter the incidence. For example, of nine cases born in the Royal Maternity Hospital, Belfast, from 1 January 1938 to 30 June 1956, six mothers were admitted either because of hydramnios or because of pre-natal X-ray diagnosis (four cases).

Secondly, from time to time cases have been reported of two achondroplastic subjects being born to normal parents. Helwig-Larson & Mørch[7] and Grebe[8]

---

[7] Helwig-Larson, H. G., and Mørch, E. G. (1950) Nord. Med. *43*, 180.
[8] Grebe, H. (1952) Z. Kinderpsychiat. *71*, 437.

have reported such instances, in one of which the parents were cousins. There are two such families in Northern Ireland, and again in one case the parents are full cousins. This suggests that there may be a recessive gene or allele, and introduces another complication.

Thirdly, there are the difficulties of diagnosis. The taller achondroplastic subjects are usually discovered only as the parents of affected children. Several cases about 5 foot in height have been reported. The writer has seen a man 5 foot 1 inch in height, and neither he nor his colleagues can decide whether this man is affected. If he had an affected relative in an appropriate relationship, the issue would probably be beyond doubt.

The separation of achondroplasia from Morquiö's syndrome is perhaps not as easy as is commonly assumed. For example, some cases of achondroplasia seem typical as far as limb-strength, shape of head and hands are concerned, yet radiographs of the spine show vertebral changes commonly assumed to be characteristic of Morquiö's disease.

Finally, as already mentioned, in the indirect estimation of the frequency of mutation, the value taken for the relative fertility may greatly alter the figure calculated. In Denmark a very high proportion of subjects have had offspring, mostly illegitimate, whereas only one subject in Northern Ireland is known to have had any children. Thus, variation in social standards would interfere with comparisons.

Epiloia

Epiloia must, it would seem, be ruled out as a marker. The total frequency of the trait as measured is low. Gunther & Penrose[9] estimate 1/120,000 and the nine living cases in Northern Ireland represent essentially the same frequency (Stevenson & Fisher[10]). It is possible to estimate that the real frequency of the genotype is perhaps three times as great, but such speculations, although no doubt valid in some contexts, are hardly satisfactory when attempting to compare two frequencies.

The trouble is that the gene may not be manifested at all or may appear only in such mild or uncharacteristic formation that the condition will not be diagnosed unless attention is called to severely affected relatives. In addition, the condition may be impossible to diagnose before the characteristic skin affections appear, and there will almost certainly be some undetectable cases in any large group of young epileptic children. When one adds that subjects suffer a very high mortality, that relatively few survive for thirty years, and that many cases of tuberose sclerosis are only discovered at post-mortem examination, the difficulties are even more obvious.

Retinoblastoma

This would seem to be a trait more suitable in many ways for the purpose of comparing frequencies, provided that there are good ophthalmological services in the areas observed. Children with eye symptoms rapidly come to the attention of the doctor, and those with the kind of symptoms and signs likely to be caused by retinoblastoma would be referred quickly to an ophthalmologist and the diagnosis would be made, if not immediately, then soon afterwards. In a very high proportion of cases the eyes are enucleated, and histological examination is available to confirm the clinical diagnosis. However, as it seems likely that as many as one quarter of eyes which are enucleated as a result of retinoblastoma are otherwise affected, biopsy examination is essential.

Falls & Neel,[4] who have made the most complete study as yet carried out are not willing to exclude the possibility that more than one gene can cause the condition and that some cases, particularly the uni-ocular ones, represent phenocopies. Further, they raise the question of racial differences in frequency by pointing to the apparently low frequency in people of African as opposed to those of European origin. Finally, they were not satisfied that they had made a complete ascertainment.

Waardenburg's syndrome

Waardenburg[11] estimated that the interesting syndrome described by him (hair pigment, eye and hearing defects) had a frequency in the Netherlands of

[9] Gunther, M., and Penrose, L. S. (1935) J. Genet. *31*, 413.
[10] Stevenson, A. C., and Fisher, O. D. (1956) Brit. J. soc. Med. *10*, 134.
[11] Waardenburg, P. J. (1951) Amer. J. hum. Genet. *3*, 195.

about 1/42,000, but he had to make allowance for an estimated proportion of undiscovered cases. Indeed, a direct estimate would involve examining the whole population for minor signs. It is clear from Waardenburg's account that, in a given subject, only one of the triad of hair anomaly, deafness and eye signs may be present, and it would seem impossible on clinical grounds and in terms of the effort required to examine sufficient people to make a direct estimate of the frequency of the trait. For example, in Northern Ireland only one case has been discovered, and this was a sporadic case which turned up in work on hereditary deafness.

Pelger's leucocyte nuclear anomaly

This appears to be an uncommon trait even in continental Europe, although it is much commoner there than in North America or in the United Kingdom.[12] Indeed, until controlled studies determine whether these apparent differences are in fact real, and if so whether they are racial or geographic, it would appear rather hazardous to suggest that the trait might be used for the purpose of comparing mutation rates. Further, in the absence of easily recognizable external characteristics it would require examination of perhaps 500,000 samples of blood to find a reasonable number of cases.

Aniridia

The syndrome of aniridia and mental deficiency is estimated by Møllenbach[13] to have a frequency of about 1/100 000. The condition appears to be inherited as a dominant, but with considerable variation down to complete failure of manifestation. The history of some families also suggests that there is a recessive form, and the pattern of aniridia and other associated eye anomalies described within and between families suggests that we may be observing the effects of several different genes or of alternative alleles. It would seem that further studies of this condition are needed before it may be considered for use for our purpose.

Multiple polyposis of colon

A mutation rate for multiple polyposis of the colon was calculated by a most ingenious method by Reed & Neel,[14] but the incidence of the condition could hardly be counted directly. The condition is one of multiple small benign tumours of the colon and rectum, and cases only come to attention (a) when one of the benign tumours undergoes malignant change and causes symptoms, (b) when there is accidental bleeding from the tumours, (c) when the colon is examined by sigmoidoscopy for some other purpose, and (d) when found by chance at autopsy.

These would have to be the starting-points for all cases of ascertainment of sporadic cases and for investigations of families in familiar cases. Short of passing protoscopes and sigmoidoscopes on perhaps ten thousand people and chasing relatives with such instruments, it seems unlikely that this condition could be used as a marker!

Dystrophia myotonica

Lynas[15] in the Department of Social and Preventive Medicines, Queen's University of Belfast, has made the only complete ascertainment of dystrophia myotonica that the writer has been able to discover. The greatest single difficulty in this condition is again failure or partial failure of manifestation of the gene and variation in age of onset, so that the mildly affected mutant phenotype or the mildly affected members of the present generation of a family could hardly be ascertained. Possibly, very careful assessment of the neurological condition of persons presenting with pre-senile cataract would make it possible to find more cases but there would still be an element of doubt about many cases.

Marphan's syndrome

Lynas (unpublished data, 1956) has also made a complete ascertainment of Marphan's syndrome. Here again, all the difficulties arise which are inherent in dealing with a trait which is the variable manifestation of an irregular dominant gene. Precisely parallel difficulties to those mentioned for dystrophia myotonica are encountered: diagnostic doubts in mild cases, the impossibility

[12] Patau, K., and Nachtsheim, N. (1940) Schr. Naturforsch. *1*, 345.
[13] Møllenbach, C. J. (1947) Op. dom. Biol. hered. hum. (Kbh.), *15*.
[14] Reed, T. E., and Neel, J. V. (1955), Amer. J. Hum. Genet. 7, 236.
[15] Lynas, M. A. (1956) Ann. hum. Genet. *21* (in press).

of ascertaining mild cases unless there are more severe cases in the family, and so on.

SEX-LINKED GENES

Of the sex-linked gene traits, only haemophilia and Duchenne-type muscular dystrophy appear to be sufficiently frequent and well-defined for possible use as markers. The question of differential mutation rates in males and females—raised by Haldane[16, 17] for both these conditions—must be regarded meanwhile as unproven. It should be remembered that we must rely on indirect estimates involving an estimate of relative fertility in calculating rates for sex-linked recessive genes.

Haemophilia

This seems to be a reasonably suitable condition for the purpose, provided that there are adequate clinical, pathological facilities for differentiating between haemophilia and allied disorders. Curiously enough, apart from Andreasson's work in Denmark[18] and possibly Fonio's inquiry in Switzerland,[19] no one has made a complete ascertainment of the condition, and with new techniques presenting opportunities of separating out different haemoglobins, such work seems overdue. The increasing life-span and fertility of haemophiliacs make for some difficulty in assessing mutation rates, but these do not seem insurmountable.

Duchenne-type muscular dystrophy

Three complete ascertainments of Duchenne muscular dystrophy have been reported. Stephens & Tyler's[20] and Stevenson's[21 22] data are strictly comparable clinically but Walton's[23] include two females, and one male who lived to 40 years of age, who would certainly not be accepted by the other authors. However, the clinical details given by Walton make it possible for the data to be equated, and there is reasonable agreement between the three on gene frequency and mutation rate, though perhaps Walton's ascertainment would seem to be less complete on internal evidence.

CONCLUSIONS

To sum up, it would appear unlikely that communities of sufficient size could be found which would have sufficiently different exposures to background radiation to permit detection, far less measurement, of differences in mutation rates.

The basic problem is likely to be statistical. In addition, however, problems in ascertainment, in clinical diagnosis and in the complexity of the underlying genetical mechanisms would add further to the difficulty in using the "single gene traits" which have been suggested as markers.

Finally, since it seems wise not to end on too pessimistic a note, the following points may be worth considering:

1. Suppose the proportion of mutations due to a background radiation of 3 r is not 10% but, say, 20%, the upper limit suggested in the report of the Medical Research Council of Great Britain.[24] Then given a population of 3,000,000 and a dominant trait with a frequency of about 1/30,000 as before, a difference of just under 5 r near the 3 r level would seem theoretically to give expected differences of the trait of about 30 cases, which might be interpreted as significant. If only 10% of the mutation rate is determined by radiation, then the same numerical difference in cases would require about 9 r difference in background radiation.

2. If, in spite of the difficulties outlined, mutation-rate comparisons are thought to be fundamental, then another type of planned observation than straight comparison between two areas might be more satisfactory. For example, serial comparisons of a number of defined areas, for several traits with carefully planned control of diagnostic standards and ascertainment, and the simultaneous collection of background radiation information would perhaps be more valuable than a comparison between two areas.

ANNEX 10

SOME PROBLEMS IN THE ESTIMATION OF SPONTANEOUS MUTATION RATES IN ANIMALS AND MAN [1]

In view of the known species differences both in the genetic structure of populations and in the apparent genetic responses to irradiation, when considering the genetic impact of increased exposure to ionizing radiation we should prefer not to attempt to extrapolate from other species to man, but rather base our thinking entirely on human data. Unfortunately, as has already become abundantly clear, the necessary data on man are not yet at hand, nor is it likely that they will be for some time to come. Under the circumstances, our thinking must for the present be guided to a large extent by what we know about the genetics of other species.

Attempts to quantitate the effects of radiation on human populations have usually been based on five factors. These are:

(1) The spontaneous mutation rate/locus/generation.

(2) The induced mutation rate/locus/*r*.

(3) The total gene number.[2]

(4) The 'accumulation factor', i. e., the ratio of nominally recessive genes already present in the population to those arising spontaneously each generation through mutation.

(5) The manner in which selection operates on the total gene complex.

Although I was asked to speak on "extrapolation from animals to man: the problem", this is so very broad an assignment that rather than utter a few

[1] Submitted by Dr. J. V. Neel, Associate Geneticist, Heredity Clinic, Institute of Human Biology, University of Michigan, Ann Arbor, Mich., USA. The material presented in this paper is drawn in large part from Chapter XV of a forthcoming monograph by J. V. Neel and W. J. Schull, entitled "The Effect of Exposure to the Atomic Bombs on Pregnancy Termination in Hiroshima and Nagasaki", and is reproduced by permission of the publishers, the National Academy of Sciences-National Research Council (USA).

[2] The product of (1)x(3), or (2)x(3), is the rate of mutuation pergamete, spontaneous or induced, as the case may be. It is possible in suitably designed experiments to estimate this directly (cf. Muller, 1955), and so decrease the number of variables involved in the calculation.

generalities about each of the factors just mentioned, and how they are manipulated to give estimates of the quantitative risks of radiation, I would like to examine in some detail the present state of knowledge as regards just one of these. The factor to be singled out for special consideration is 'spontaneous mutation rates'. There is no deep significance in the choice of this topic, i. e., any one of the four other factors of importance to attempts at extrapolation might almost equally well have been chosen for detailed consideration. In what follows, attention will repeatedly be drawn to gaps in knowledge. This should in no way detract from the past accomplishments of investigators in the field, but is submitted in the belief that the primary purpose of this meeting is to discuss what remains to be done if we are to place in proper perspective the genetic risks of ionizing radiation to human populations.

Current thinking concerning the rate of mutation of mammalian genes is for obvious reasons strongly influenced by what is known concerning drosophila rates. No less pertinent, but more difficult to fit into our conceptual framework for man at present, is the extremely important data emerging from the study of other inframammalian forms, such as the recent work on bacteriophage of Benzer (1955). We will accordingly first consider briefly what seem to us to be some of the more pertinent data concerning drosophila. For methodological reasons it is customary to distinguish on the basis of their physiological effects between three categories of mutations, namely, those associated with visible effects, those associated with lethal effects, and those which express themselves through a reduction of viability in the absence of detectable somatic effects, the so-called semi-lethal mutations (1–10 per cent. viability) and deleterious mutations (over 10 but less than 100 per cent. viability). Terminology in this field leaves something to be desired. Thus, the 'deleterious' mutations must have an organic basis, so that many of them would be found on careful study to be also 'visibles'. By the same token, most 'visibles' are also 'deleterious'. Finally, the dividing line between 'lethals' and 'semilethals' may be altered by culture conditions. Be that as it may, the division into these three categories has an operational usefulness, as we shall now see.

Beginning with the pioneer attempts of Muller (1934; see also Kerkis, 1935) and Timoféeff-Ressovsky (1935) a number of efforts have been made to establish the relative frequencies with which these types of mutations are represented among all mutations. These attempts have involved radiation-induced rather than spontaneous mutations because of the much more laborious nature of the problem if attacked through the study of spontaneously occurring mutations. In view of the possibility that the relative frequency of lethals is higher among the radiation-induced mutations because of the increased proportion of minute deletions, the estimate of the ratio, (semi-lethals + deleterious)/lethals, may be a minimum estimate. Muller (1954; see also Falk, 1955) places this ratio at 3–5 to 1. This same author goes on to state that ". . . the ratio may indeed be considerably higher than this, since the technique was hardly refined enough for the detection of detrimentals with a viability greater than some 85 per cent. of normal. Other studies have shown that 'invisible' mutants causing sterility or lowered fertility of some degree also form a very large group. This group, however, overlaps, to an extent not yet well investigated, that of the detrimental mutations (p. 396).

The significance of information concerning the relative frequency of mutants with viability in the 85–99 per cent. range in attempts to quantitate the genetic risks of ratiation is of course enormous. A related problem concerns the frequency of mutations for which the organism *at the time* is able to compensate completely, the undetectable mutations. Lately considerable attention has been directed towards the genetic basis and evolutionary implications of physiological homeostasis (refs. in Lerner, 1955). The possibility cannot be ruled out that the principle of homeostasis enables some organisms to compensate entirely, under particular sets of circumstances, for the effects of certain mutations.

It may be argued that there is no reason to be concerned about the relative frequency of mutants with undetectable effects in a consideration of the deleterious effects of radiation. However, these mutations are undetectable only under the conditions set by the observer. Under other conditions, set by nature and not by man, they might have decided effects. It is not at all difficult to argue that the mutants with over 85 per cent. viability which cannot now be studied in drosophila may in evolutionary importance far outweigh the visibles.

Muller (1950), in a discussion of the question of the numerical relationship between lethals, on the one hand, and semi-lethals and deleterious mutations, on the other hand, has made the following statement: "However, studies carried

on in drosophila during the past year by Meyer, Edmondson, and the writer indicate that in this organism the assumption of an equal distribution of detrimental mutations throughout all i_{ho} values[8] (when represented on an arithmetic scale) does not hold. Instead, it appears that, following the high but descending peak formed by complete lethals (i_{ho}=100 per cent.) and nearly complete lethals (i_{ho} = between 98 per cent. and 100 per cent), there is a marked drop in the frequency of mutations. The mutations studied were induced in an autosome (the second chromosome) by ultraviolet light acting on an interphase stage (in the polar cap). Along with 208 complete lethals there were 20 mutants found in the range of i_{ho} between 98 per cent. and 100 per cent., and again only 20 in the range of i_{ho} between 90 per cent. and and 98 per cent., although this range is four times as wide as the preceding one. If the rest of the distribution, as far as i_{ho}=10 per cent. had only the same frequency of mutations as in the range between 90 per cent. and 98 per cent. there would have been only 240 detrimentals in the entire interval between 100 per cent. and 10 per cent. to set against the 208 complete lethals found. But since we know from other work, previously cited, that the detrimentals in this interval are in reality several (about five) times as numerous as the complete lethals, it is evident that their frequency must, at lower degrees of detriment (lower i_{ho}), rise very much above that existing in the 90 per cent. to 98 per cent. range. The distribution of frequencies of i_{ho} therefore forms a bimodal curve with one peak at the left origin, lethality (i_{ho}=100 per cent.), and another peak somewhere to the right.

"Little more than this is yet known definitely about the shape of the curve in question, important though this genetic question is. However, there are grounds, both theoretical and observational, for regarding it as very unlikely that the second peak is near the first or that the rise towards it is sharp. Hence it is probable that detrimental mutations, instead of having an even distribution with respect to values of i_{ho}, form a curve which, except for its peak of near-lethals at the left end, is massively skewed towards the right, with its mean at a value of i_{ho} significantly beyond the middle (0.5)." (pp. 140–141).

If we consider these remarks of Muller in conjunction with the possibility of 'invisible' mutants discussed earlier, then the problem of estimating the relative frequency of lethal mutants versus those viable to some degree assumes new complexity. Fig. 1 attempts to present some of this complexity graphically. The abscissa of this figure represents viability of the homzygous genotype in some arbitrary environment. In this connexion, it is apparent that the term 'lethal' is relative, some lethal mutations having effects under no known circumstances compatible with life, other lethal mutations having far lesser effects. Likewise, the term 'normal' as applied to viability is relative, some normals being more normal than others, with the differences brought out only under unusual circumstances. Thus far, observations have been limited to the range of lethality and 1–85 per cent viability. As Muller has pointed out in the statement quoted above, there is great doubt concerning the shape of the curve of numerical relationships within this range. We have indicated two of the principal alternatives. Curve A assumes a mode at 60–70 per cent. viability, from which it would seem likely that the proportion of mutations in the 85–100 per cent. and normal viability range is small. Curve B assumes that the mode is farther to the right with the corollary that there is a considerable group of mutations not now being detected. How large that group is depends of course on the shape of the curve.

The question of the relative frequency of lethal mutations as contrasted to visibles, is on somewhat more secure footing than the question of the ratio of lethal mutations to mutations reducing viability to a lesser degree. In tabulating the results of radiation experiments by five different workers, Schultz (1936) found this ratio to be 7.4:1. In view of the well-recognized differences in the ability of individuals to recognize mutant phenotypes, the true ratio is probably somewhat lower. We refer, for instance, the ratio of 5.2:1 which obtained in the extensive and meticulous experiments of Spencer & Stern (1948). Even this ratio may be too high. Thus, in the control cultures, Spencer & Stern obtained a ratio of sex-linked lethals to visibles of 4.3:1 and in the irradiated cultures, a ratio of 5:3:1. In a study on spontaneous mutations in a 'high mutation rate' line, the ratio of sex-linked lethals to visibles was 3.6:1 (Neel, 1942). The ratio of visibles :lethals :semi-lethals and deleterious mutations may, as an approximation, be said to be someplace between 1:4:16 and 1:6:30, with, as noted above, the most uncertainty centring about the magnitude of the third figure in the ratio.

[8] i_{ho} = the amount of impairment produced by a gene when homozygous.

The important question of the mutation spectrum at individual loci remains in its early stages because of the amount of labour involved in securing reliable data. The effort involved in studying this problem through the use of spontaneously occurring mutations appears almost prohibitive. Attempts to study the problem using induced mutations again encounter the question of how precisely the mutational spectrum obtained with mutagenic agents parallels that derived from the study of spontaneous mutations. However, there is some preliminary evidence that the ratios just given may vary significantly from locus to locus. Thus, although there are many instances of lethal and visible mutations arising at the same locus, there are also some few cases in which a locus does not appear to be essential to life, in the sense that flies with a deficiency for this locus may live although they are of reduced viability (e. g., yellow and achaete, Muller, 1935). These loci, then, would not produce at least one type of lethal mutation. Finally, for methodological reasons, localizing 'deleterious' mutations to specific loci is extremely difficult, so that studies relating these to the loci producing lethals and visibles are in an early stage.

It should also be pointed out that the question of the total relative frequency of mutation at different loci is in a very unsettled state. Although there seems no doubt that the rate of recovery of mutations differs from locus to locus, care must be exercised in reasoning as to the magnitude of the true differences (cf. Neel & Schull, 1954). In the following discussion of mutation rates at specific loci, the fact that these are *selected* loci must constantly be borne in mind.

With respect to the rate of occurrence of spontaneous 'visible mutations' at specific loci in drosophila, data are available from five extensive series of observations. These are summarized in Table 1. Time does not permit us to give this table the detailed attention it deserves. In most of these studies, some 'special circumstance' occurred that requires at least very brief mention. Thus, Muller, Valencia, & Valencia (1950) observed in other experiments with the same strain used for their 'visible mutation' series that the rate of occurrence of sex-linked lethal mutations in this strain was 0.7 per cent., a rate some fourfold greater than usual. From this they argue that "the frequency of gene mutations at the nine loci would *ordinarily* average between 10^{-5} and 7×10^{-6} per locus in females" (p. 125). However, in view of the possibility that these 'high mutation rate' lines contribute significantly in nature to the total of spontaneous mutation (Ives, 1950; see also Neel, 1942), it seems appropriate simply to average this finding with the others. From the data of Glass & Ritterhoff (1956), it would appear that the mutation rates of males are higher than females, but this is scarcely substantiated by the difference in the findings of Alexander (1954) and Muller, Valencia, & Valencia (1950). Accordingly, we have simply averaged all the findings without regard to sex. No attempt has been made to take into account the effect on the observed results of possible differences in the age of the flies tested. The paper of Glass & Ritterhoff contains additional data on mutation rates emerging incidentally to their study—it has seemed preferable in this summary to utilize only data on loci 'pre-selected' for mutation rate estimates. It would appear that Muller et al., and Schalet, did not score as mutants flies with mutant phenotypes which were infertile, whereas Glass & Ritterhoff did. In any mutation rate study, a considerable proportion of apparent mutants prove sterile. Schalet encountered one 'cluster' of ten 'cut' mutants, presumably due to a mutation occurring in a spermatogonium. One can argue as to whether this should be scored as 1 or 10 mutations in the context of the present discussion. Finally, in all these studies where mutation gives rise to one mutant in a culture of wild type, there is the question, probably not so serious in studies on man, of the extent to which the less vigorous mutants are eliminated prior to the inspection of the culture, and the further problem of the human factor in recognizing the mutant.

While, then, it is possible to 'correct' the data of Table 1 in several ways, I have made no attempt to do so. In a total of 4 625 945 locus tests, at least 41 mutations were recovered, a rate of 0.9×10^{-5}. However, *this applies only to 'visible mutations', or to lethal and deleterious mutations which in combination with a mutant allele have visible effects.* If other lethals, semi-lethals, and deleterious mutations are arising at these same loci which are without detectable visible effects with the test-crosses employed, the mutation rate must be higher. There is no way at present to estimate the amount of mutation not detected with current specific locus techniques, but if, for instance, the ratio of visibles/

(undetected lethal+semi-lethal+deleterious+sterile mutations) at these loci were as high as 1:4, the mutation rate per locus becomes 4×10^{-5}. In other words, there are some grounds for feeling that the commonly quoted mutation rates for specific loci for drosophila are conservative. If, on the other hand, the mutation spectrum at specific loci is restricted, as some evidence suggests it to be in the sense that some loci give rise predominantly to 'visibles' and others to 'deleterious' mutations, then the 'true' mutation rate may be closer to the 1×10^{-5} which emerges from specific locus studies than the 4×10^{-5} just suggested.

Two other studies involving individual loci should be quoted. Lefevre (1955), in a paper which contains an excellent discussion of the problem of estimating spontaneous mutation rates, reports that the rate of appearance of mutants with visible or lethal effects at the *y* locus is "about 1 per 75,000" (p. 379). On the other hand, Bonnier & Lüning (1949), in a paper criticized by Muller (1954) because the rate of recovery of spontaneous mutations appeared to be too low in comparison with certain other findings, observed only one mutation at the white and forked loci among 153 579 flies tested for visible mutations, a rate of 3×10^{-5}. Again, both of these estimates do not take into account the semi-lethal and deleterious mutations which may not be detected by the techniques being employed.

Utilizing a somewhat different approach, Dobzhanzky, Spassky, & Spassky (1952) have estimated the average rate of mutation to lethals, semi-lethals (1–20 per cent. viability), and visibles *per lethal producing locus* in different species. These estimates, which they felt are more likely to be overestimates than underestimates, are reproduced in Table 2. Again, the estimate does not include the deleterious mutants.

In summary, then, it would appear that depending on one's view of the representativeness of the loci studied, and the problem of the relative frequency of mutations not detected by current techniques, there is room for a divergence of opinion concerning the average rate of mutation of drosophila genes, with the range of possibilities perhaps extending from 0.5×10^{-5} to 5×10^{-5}. In our opinion, even this range of estimates must be applied with great caution to human problems.

Turning now to mammals, we find that significant studies are available for only two species, the house mouse and man himself. The figures for the house mouse were derived in much the same fashion as the figures quoted for drosophila, namely, through a search for mutant individuals among animals simultaneously heterozygous at multiple loci. Russell (1954), in connexion with his important observations on radiation-induced mutations in the house mouse, has found that in his control material the rate of appearance of *visible* mutations in 265 076 locus tests was 0.8×10^{-5}. The observational error is of course large. Again it must be recognized that these tests very probably detect only a fraction of the mutations occurring at these loci.

There seems no reason to labour further the point that our knowledge of spontaneous mutation rates at specific loci is poor for any species. In some attempts to extrapolate from non-human material to man, the additional problem arises of the greater life span of man than of laboratory material, as well as the question of the type of species which man represents in terms of mutation rate. While I would be the first to defend the animal work as providing the best estimates available at the present time, it is my opinion that in the final analysis, we must have figures for man himself.

The available estimates for the frequency of occurrence in man of certain mutations with visible effects have already been summarized by Professor Stevenson and Professor Penrose. Many of the problems involved in estimating human mutation rates have been discussed by these two authors as well as previously (Haldane, 1948, 1949; Neel (1952) Neel & Schull, 1954; Nachtsheim, 1954) and will not be re-examined here. The average of the available estimates of the rate of mutation for the autosomal dominant and recessive sex-linked mutations thus far investigated in man is in the neighborhood of 2×10^{-5}/locus/generation. These estimates, now, are entirely limited to mutations with visible effects. Because of the nature of the design of observations on human mutation rates, it seems possible that a higher proportion of the mutations at the specific loci being studied is going undetected in man than in Drosophila. There is no way to estimate the magnitude of this difference at present, but a total mutation rate as high as 1×10^{-4} at these loci is a possibility. Although the

apparent correspondence between human and *Drosophila melanogaster* rates is noteworthy, because of the differences in the way the rates are obtained one must be cautious in the emphasis placed on the similarity. However, if the correspondence were indeed valid, this has interesting implications concerning the importance of 'aging' and failures in the 'copying process' at mitosis, and the role of background radiation, in spontaneous mutation rates.

The representativeness of these estimates for man has been repeatedly challenged. There can be no doubt that there is definite selection in the loci studied. How this influences our estimates is not at all clear. As we have pointed out elsewhere (Neel & Schull, 1954), mutation at any particular locus may be thought of in terms of these aspects: (1) the frequency of mutation at that locus; (2) the number of alternative forms of the gene which may occur at any locus, i. e., the number of multiple alleles; and (3) the ease with which the effect associated with each of these multiple alleles can be detected. We assume that some loci are more mutable than others because we detect the results of mutation more frequently at these loci. However, making allowance for 'unstable loci', the hypothesis has not been disproven that the inherent instability of all genes is, by virtue of their biochemical complexity, very similar, but that the results of mutation are more readily detected at some loci than at others because of the role of that particular locus in the animal's physiology. It is entirely conceivable that the loci[4] thus far selected for study in man are those at which a high proportion of all possible alleles at that locus results in readily detectable effects, but at which the per locus mutation rate is fairly representative of the human species.

For purposes of calculation, estimates of the rate of mutation of human genes have included 10^{-4} (Evans, 1949), 10^{-7} (Wright, 1950), and 2×10^{-5} (Muller, 1950; Slatis, 1955). In the current state of our knowledge, students of the problem can select and justify estimates differing from one another by a factor of 100.

If time permitted, we would do well to submit to the same kind of scrutiny our knowledge concerning the other factors that enter into quantitative treatments of the risks of irradiation, namely, (1) induced mutation rates at specific loci, (2) gene number (or, alternatively, gamete mutation rates), (3) the accumulation factor, and (4) the manner of action of selection. This will obviously be impossible. However, in closing I would like to say just a few words about the nature of selection in human populations. To begin with, there would seem to be little problem in extrapolating from animals to man, since there is practically nothing known concerning the detailed action of selection in animal populations on which to base an extrapoliation. For all our allegiance to the principal of natural selection, it is amazing how little we know of its actual detailed workings. True, it is easily demonstrated in experimental populations that grossly defective individuals seldom reproduce. But the problem of how the population as a whole maintains its fitness is virtually untouched. To mention only one important point, to what extent does the stability and adaptability of the species rest on the mechanism of balanced polymorphism, a mechanism not readily disturbed by an increase in mutation rates?

There is one final point I should like to emphasize. In our attempts to evaluate the genetic risks of increased radiation to the human species, I am a strong proponent of extensive animal experimentation. Through such work, possibilities can be explored which would either involve prohibitive amounts of time or be impossible for man. But when differences do appear between two animal species, as is already the case, only work on man will tell which of the species he resembles more closely. It is of tremendous significance to the practice of medicine and the development of atomic energy whether the 'permissible' population dose above background is 3 *r* or 30 *r* per generation. In reaching any final conclusions concerning permissible radiation doses in man, regardless of what is learned concerning other animal species, we must have accumulated far, far more data on man himself than are now available.

---

[4] In point of accuracy, we do not know but what any particular mutation rate study in man is detecting mutation at several loci.

TABLE 1.—*Frequency of occurrence of spontaneous "visible mutations" in various species*

Author	Chromesome	Number of organisms	Number of loci	Total locus tests	Mutations	μ
Drosophila:						
Muller, Valencia, & Valencia, 1950.	X (females)	±60,000	9	540,000	15	2.8×10^{-5}
Altenburg, after Muller et al., 1950.	X (females)	±50,000	8	400,000	0	0
Alexander, 1954	III (males)	45,504	8	364,032	0	0
Glass & Ritterhoff, 1956	Multiple (females)	100,414	4	401,656	1	2.5×10^{-6}
	Multiple (males)	102,759	[1] 4	359,657	17	4.7×10^{-5}
Schalet, unpublished	X (males)	111,600	14	1,562,400	[2] 6	0.4×10^{-5}
	X (females)	71,300	14	998,200	2	0.2×10^{-5}
				4,625,945	41	0.9×10^{-5}
House mouse: Russell, 1954	Several	37,868	7	265,076	2	0.8×10^{-5}

[1] 1 sex-linked.
[2] One of these mutants appeared as a "cluster" of 10 flies. If one is concerned only with the rate of recovery of mutant phenotypes, then the entry here should be 15, and the average of the five studies quoted becomes 1.1×10^{-5}.

TABLE 2.—*Estimated average mutation rates per lethal-producing locus in several drosophila species, after Dobzhansky, Spassky, & Spassky (1952). These estimates are felt by the investigators to be more likely overestimates than underestimates*

Species	Second Chromosome	Third Chromosome
D. Melanogaster	1.1×10^{-5}	
D. pseudo-obscura		1.1×10^{-5}
D. willistoni	2.2×10^{-5}	3.0×10^{-5}
D. prosaltans	1.1×10^{-5}	2.1×10^{-5}

EFFECT OF INBREEDING LEVELS OF POPULATIONS OF INCIDENCE OF HEREDITARY TRAITS DUE TO INDUCED RECESSIVE MUTATIONS [1]

It is well known that the incidence of hereditary traits in populations depends not only on the respective gene frequencies, but also on the breeding structure of the populations. One of the important aspects of the prevailing mating pattern can be measured through the use of the coefficient of inbreeding, a population parameter practically impossible to evaluate in natural populations of animal species, but very easily determined in man.

INBREEDING IN BRAZIL

During the past six years, the writer has become very interested in this particular problem in human genetics and has tried to discover the inbreeding levels under which the present-day Brazilian populations live, as well as the magnitude of the same parameter during the last 150 years. The study of this problem in Brazil is greatly facilitated by the fact that much data can be obtained through the analysis of Catholic marriage records, a source of information which is available for the great majority of the population. The calculation of the coefficients of inbreeding has been done on the basis of data on the frequencies of marriages between uncles and nieces, aunts and nephews, first cousins, first cousins once removed, and second cousins. A few of the results obtained have already been published (Freire-Maia [2,3,4]), but the great bulk of the data will be presented in a paper now in preparation.

The following features of the breeding pattern of Brazilian populations have become apparent:

1. The degrees of inbreeding vary greatly in different regions: the rates are relatively low in the south and in parts of the east (a mean level of about 1% of first-cousin marriages has been found); are very high in large regions of the east and north-east (a level as high as 10% for first-cousin marriages has been detected); and are intermediate, but highly variable, in other regions.
2. There is, in general, a clear trend towards decreasing inbreeding rates, although a few reversals of this trend have been noted.
3. Geographic inbreeding gradients have been detected in some zones, with increasing inbreeding from the coast to the hinterland.
4. Although some of the Brazilian rates of inbreeding are higher than the highest so far found in other countries, the mean Brazilian coefficient of inbreeding (0.002) is relatively low because about one-third of the population lives at the level of 1% of first-cousin marriages.

An analysis of the factors probably responsible for the different degrees of inbreeding found in Brazil revealed that cultural pattern, economic level, migration, population density and degree of ruralization seem to be the most important.

EFFECT OF INBREEDING ON POPULATION STRUCTURE

It is known from theoretical analysis that inbreeding coefficients as high as 0.01 and 0.02, such as are found in some localities, produce negligible effects on common recessive traits, but have a considerable influence on the rare ones (Table I). Suffice it to say, for instance, that characteristics with a gene frequency of 1% will, under the action of a coefficient of inbreeding of 0.01 (which prevails in large populations in Brazil), have phenotype frequencies 99% greater than those expected in a model assuming no inbreeding (Table I) and 90% greater than those expected in populations with a coefficient of inbreeding of 0.001 (Table II). These almost 100% increases could hardly be detected in a direct way, through the analysis of the phenotype distribution in the populations, but may be appreciated through the incidence of the so-called "recessive" diseases in the offspring of consanguineous marriages, as well as through the incidence of consanguineous marriages among the parents of people presenting the same kind of genetic traits. Some data obtained on deaf-mutism show, for instance, a really very high inbreeding effect. In a population where the frequency of

first-cousin marriages has been estimated as 3.5%, there has been shown to be about 21% of first-cousin marriages among the parents of deaf-mute children (Aguiar & Freire-Maia[5] and unpublished data). Inasmuch as some of these children undoubtedly owe their defect to extrinsic factors, the frequency of consanguinity among the parents of children with genetically determined defect is of course even higher. This problem will, however, be discussed in detail elsewhere.

EFFECT OF INBREEDING UNDER INCREASED MUTATION RATE

In recent times one of the most important human genetics problems is the evaluation, on a quantitative basis, of the effects of increasing radiation levels on the genetic composition of populations. Unfortunately, no accurate mathematical treatment could be given to this subject up to the present, as no precise information has yet been collected on some basis phenomena—namely, the spontaneous mutation rates, the induced mutation rate per gene per roentgen, the total number of loci, etc. (see discussion in Neel & Schull[6]). Thus the treat ment to be presented below is *not* intended to show what happens under increasing radiation, but what could happen under increasing inbreeding. The emphasis will be put *not* on the rates of mutation frequency increment but rather on the fact that, assuming a given increment, the action of different inbreeding rates will produce different quantitative effects.

For instance, assuming that the probability of induced mutation per gene per roentgen in man is of the same order (2.5×10^{-7}) as that found in the mouse (Russell[7]), doses of 100 r would increase this probability to 2.5×10^{-5}. Thus, five different populations (A, B, C, D, and E), differing only in the intensity of inbreeding, with two given recessive genes at frequencies of 0.007 and 0.003, will have the frequencies of these genes increased respectively to 0.007025 and 0.003025. However, the increase of the frequencies of the recessive genotypes will depend on the inbreeding level of each population (Table III). Five inbreeding coefficients have been chosen for comparison: 0.001, 0.003, 0.006, 0.009 and 0.011. The first one, representative of European populations according to Haldane,[8] also holds true for southern Brazil; the third has been assumed to characterize the highly inbred Japanese populations as a whole (Neel et al.[9]); the fourth is the highest detected Brazilian coefficient for a large zone (the centre of the north-eastern region); the fifth is probably the coefficient now prevalent in the populations of this particular zone; and the second has been selected to represent an intermediate step between the "low" European level (0.001) and the "high" Japanese one (0.006). Table III shows how much different coefficients of inbreeding may change the phenotype composition of populations subject to the same radiation impact. With the initial frequency of 0.003, it is seen that the Brazilian coefficients 0.009 and 0.011 produce total increments (0.01125 and 0.01275) more than twice as great as that produced by the European and southern Brazilian coefficient of 0.001. With the initial frequency of 0.007, the effect is a little smaller. The action of the Japanese mean coefficient is somewhat intermediate, as expected. Other things being equal, then, it is to be expected that induced recessive mutations manifest their effects with much higher frequencies in populations with inbreeding rates like those found in some Brazilian regions than in some European or North American populations.

PROSPECTIVE GENETIC RESEARCH ON INBREEDING

Now that we possess the basic information on inbreeding rates in Brazil, it has been possible to discover some "modern" populations living at inbreeding levels probably comparable to those of European communities in the Middle Ages. In the focus of the highest inbreeding levels in Brazil, for instance, some localities have been found where as many as 1 out of 6 and 1 out of 5 of the marriages are contracted between first cousins, and 1 out of every 3 marriages is consanguineous up to and including second cousins. This situation would seem

to be of great potential usefulness in the study of the general effect of consanguineous marriages on the genetic make-up of populations and the discovery of the mean number of deleterious recessive genes per individual. Unfortunately, in the zones in Brazil where the very high inbreeding rates prevail, no analysis regarding the incidence of specific hereditary anomalies seems feasible because the level of medical practice there is lower than in the larger cities. Nevertheless, in these regions a study can be made of such population characteristics as the frequencies of abortion, miscarriage, stillbirth, infant mortality, malformations as a whole, etc., and should afford some interesting results. Furthermore, in Rio de Janeiro, Sao Paulo, and some other cities, where the inbreeding rates are probably from ten to twenty times higher than those prevailing in similar or even smaller cities in the USA (Glass;[10] Herndon & Kerley;[11] Steinberg (personal communication, 1956); Woolf et al.[12]), and where very good hospitals exist, a complete and detailed analysis is possible.

ACKNOWLEDGMENT

The writer is indebted to Dr J. V. Neel and Dr J. N. Spuhler for discussions in connexion with the preparation of this manuscript.

ANNEX 12

DETECTION OF GENETIC TRENDS IN PUBLIC HEALTH [1]

To assess the practical genetic consequences of irradiating human populations, one must either: (a) extrapolate from mutation-rate studies in exposed animals, or men, to the effects of the additional mutations on human health and fitness; (b) extrapolate from fitness studies in animals to health and fitness in man; or (c) measure the important changes in the genetic component of health and fitness directly in the human populations which are exposed to a rising background of radiation.

The first two of these approaches have received considerable emphasis because the experimental procedures are relatively straightforward, and because predictions are needed, however tentative they may be. Unfortunately, however, it is extremely difficult to extrapolate from increases in mutation rates to the magnitude of the resulting increases in amount of general ill health, or from the fitness of animal populations to the fitness of human populations. In fact, there is reason to doubt whether the extent of the effect of a given increase in background radiation can ever be adequately anticipated.

The logical complement to prediction lies in the development of some sensitive means of detecting important genetic trends before they have gone too far. Ultimately, of course, this detection is the only way our predictions can be tested.

The main deterrents to setting up a continuing survey aimed specifically at the detection of important long-term genetic trends are the absence of any certainty as to how sensitive a method can be devised, and the very considerable financial and organizational difficulties. However, since we lack the assurance that "prediction" alone will fill our needs, it seems important that the feasibility of "early detection" receive much fuller consideration than it has in the past.

The present account deals with the application of certain of the methods of vital statistics to such detection. It seems essential to make it quite clear that the suggestions which follow are not at present recommended lines of action for general adoption by central vital statistical or record departments. These suggestions have been made earlier with Canada, solely as personal recommendations, with a view to studying their feasibility. As presented here, however, the remarks are designed simply to show the possibility of collecting specific data on human variation which could not possibly be assembled on a comparable scale by the conventional *ad hoc* field inquires used in population genetics. The methodology is discussed in this paper in the hope of getting constructive criticism before we embark on research on such a large scale.

Sources of Information

In general, to discriminate between genetic and environmental causes (either in genetic conditions of individuals or in population trends) information is needed concerning the number of affected and unaffected individuals, their family relationships, and the environments to which they have been exposed. Considerable information of all three kinds exists in the routine registrations of births, deaths and marriages. The handling procedures are not at present designed to discriminate between the genetic and environmental contributions to the diseases which are reported on the death registrations, but if maximum use were made of all three kinds of information we could presumably make such a distinction, with at least some degree of success.

Since routine vital statistics are a recognized measure of the health of a population, one approach to the detection of genetic trends would seem to lie in supplementing the basic information where necessary, and in designing handling procedures to distinguish the genetic from the environmental causes of ill health.

The approach is limited at present with regard to the health information, which relates solely to causes of death and still-birth, but other routine sources could be tapped. For example, one Canadian province (British Columbia) has made use of the "Physician's Notices of Births and Stillbirths", which are quite separate from the birth registrations, to obtain details of still-births and congenital abnormalities. The problem of adequate ascertainment is undoubtedly soluble.

The chief advantage in the use of registrations of births, deaths and marriages, however, is that these contain, in raw form, the most reliable and complete information on the family relationships of the individuals who make up the population. They are in essence a family tree on a very large scale (complete with marriage dates, birth dates, and the dates of all deaths). To extract this family information manually, and to convert it into a usable form, would be a prodigious task, and for this reason we have concentrated much of our thinking on the development of mechanical procedures involving the matching and sorting of punch cards to form a "Family Register Index".

A "Family Register" would contain cards for all marriages, starting from a given year. To these would be added the cards for all births arising out of these marriages, which would be identified and sorted into their respective sibling groups. In addition, all cards for still-births and for the deaths of offspring would be similarly identified and sorted. A further procedure has been devised whereby any marriages between first cousins could be identified, together with the births and deaths of their offspring, without resorting to interviews and without reference to any other kind of record (see Fig. 1 and 2).

Thus, for each disease condition on which information is available, it would be possible to determine the incidence within three groups of individuals: the population as a whole, the offspring of first-cousin marriages, and the siblings of affected individuals. This seemed the most suitable use to make of the family relationship data in an initial study, but the information could be applied in many other ways.

In addition, the registrations contain a considerable amount of routinely recorded information on environment, which would permit a breakdown of any data by the following factors: rural or urban residence; socio-economic class, as derived from father's occupation; age of mother and of father at time of birth; family size and spacing; racial origin; gestation period; legitimacy or illegitimacy; and home *versus* institution birth. This is probably adequate for any initial study, and supplementary information could undoubtedly be obtained.

The "Family Register Index" is the one unique feature of the present proposals. In emphasizing the mechanical methods involved, it should be explained that it was felt that the personal-interview technique of obtaining pedigrees would become too laborious in any study involving both a large population and many of the common diseases. And yet, if the common diseases were not included, or if the study were limited to a few genetically simple "indicator conditions", it would be difficult to relate any trend observed to the general health of the population. And the latter is, of course, our ultimate practical concern.

In making these proposals it has been assumed that the present problem of genetic damage from radiation, and the related problem of the operation of other causes in the production of genetic trends, are of sufficient importance to justify any appropriate changes in the collection and analysis of statistics relating to the health of the whole population. Our prime concern is with broad categories

of ill-health, and methods of obtaining and handling information on the very large numbers of affected individuals and their relatives need to be developed.

Rationale

In general, the greater the complexity of the genetic and the environmental causes of a condition, the more information of the three kinds (i. e., pertaining to health, family and environment) will be required to disentangle the two.

Thus, to look for a trend in the frequency of a simple dominant "indicator" condition, it would only be necessary to observe the proportions of affected individuals in the population. And to detect trends involving a simple recessive gene it would be sufficient to know the proportions of affected individuals in offspring from consanguineous parents. However, if one extends the survey to conditions arising from a recessive gene with incomplete penetrance, it would be necessary, in addition, to know the corresponding proportion of affected individuals in the rest of the population. In this case the gene frequency would be calculated from the ratio of the two, referred to as a "K" value; and since penetrance affects both components of the ratio equally, both "K" and the calculated gene frequency would be essentially independent of penetrance.

The number of diseases can, of course, be extended still further to include those due to dominant genes of unknown penetrance and those due to multiple additive genes, using comparisons between siblings (or other closely related individuals). Formulae for the estimation of gene frequencies from data of this kind (using the ratio of the incidence in close relatives of affected individuals to that in the population as a whole, i. e., a "K" value) have been derived by Penrose[1] and applied to a number of common diseases.

Where our main interest is in the detection of changes in the gene frequencies, rather than in the absolute frequencies, the problem is considerably simplified. Attention centres on trends in the values of "K", and it is not essential to know whether the genes are recessive, dominant, or multiple additive.

Thus, a basic requirement for discriminating between the genetic and the environmental trends affecting public health is a knowledge of the proportions of affected individuals within three groups of people: the offspring of consanguineous unions, the close relatives of affected individuals, and the population from which these were drawn.

Environmental changes, when they affect penetrance uniformly throughout the population, are unlikely to produce spurious trends in the estimates of gene frequencies. This is true also of changes affecting the extent of the ascertainment, and of changes in diagnostic fashion, when they occur uniformly throughout the population. However, there are a number of sources of error, and additional information would be needed in order to detect and evaluate them. Such information would relate mainly to the environment.

Gene frequencies based on consanguinity data would be least subject to bias, the main source of which is the fact that marriages between close relatives tend to be more common in certain sectors of the population—notably, the rural groups. To eliminate errors from this source it would be necessary to obtain independent values of "K" from the various population groups (e. g., breaking the data down by: rural or urban residence; racial origin; socio-economic class; etc.) or, better still, from comparisons with offspring from the brothers and sisters of the individuals who married their cousins.

Gene frequencies based on "K" values for sibling comparisons may be biased in a number of ways. In general, where there are family-to-family differences in environment affecting the expression or penetrance of an hereditary disease, the increased tendency for affected individuals to appear within particular families will increase the value of "K" and bias the estimate of gene frequency downwards. Environmental heterogeneities which might give rise to this kind of bias could be associated with: (a) maternal effects due to the mother's hereditary constitution; (b) maternal effects due to the environment to which the mother has been exposed; and (c) effects due to the child's post-natal environment. It should be possible to detect any bias from these sources, and to estimate its magnitude.

Thus, where there are maternal effects due to the mother's heredity, these should make for a closer resemblance between the children and any of their first cousins by their mother's sisters, than with first cousins of the other three kinds (i. e., offspring of the mother's brothers, of the father's sisters, or of the father's

[1] Penrose, L. S. (1953) Acta genet. (Basel), 4, 257.

brothers). The extent of the discrepancy (allowance having been made for differences in the likelihood of inheriting similar X-chromosomes) should indicate the magnitude of the bias. Important environmental variables other than inherited maternal effects should be strongly correlated with the incidence of the condition in a suitable breakdown by environmental groups.

Environmental differences may operate by altering either the expression of a genetic condition (i. e., the "penetrance" or "expressivity") or the production of non-genetic effects which simulate the genetic condition (i. e., "mimics" or "phenocopies"). Variations in environment might tend to group the affected individuals into families by either mechanism, thus increasing the value of "K" and causing the gene frequency to be underestimated. But variations in the production of mimics could operate in the opposite manner through obscuring the grouping due to genetic causes. Both environmental influences will be observed in an appropriate breakdown of the data, as a correlation between environmental group and incidence of affected individuals.

The two effects will in many cases be distinguishable, however, by observing the "K" values for appropriate environmental groups. Where the influence is on penetrance, the value of "K" for any homogeneous group will tend to be less than that for the mixed population (and the estimates of gene frequency will be less biased). Where the influence is on mimic production, the value of "K" for a genetic condition would tend to be increased in homogeneous favourable groups where mimics are rare, and decreased in the unfavourable groups where they are common. In either case, the most reliable estimates of gene frequency would be obtained from groups living in the most uniformly favourable environments.

Such refinements, using information which is already collected as a matter of routine, would remove many of the sources of bias. Further, since genetic applications were not envisaged in the planning of the present system of vital statistics collection, improvements could undoubtedly be devised after any major attempt to apply the existing information. It is, of course, impossible to predict just how sensitive a means for the detection of genetic trends might eventually be developed; this can only be done as experience is gained in using the information which we already have in a readily available form.

In case the present proposals seem over-optimistic, it is worth noting that at least one serious attempt has already been made to detect a genetic trend in a complex quantitative character (namely, intelligence[8]) which is known to be subject to environmental influences, and that this attempt has made very little use of information on family relationships and environment, and of the refinements which these permit.

DETAILS OF FACILITIES AND PROCEDURES

Microfilms of the registration forms for all births, deaths and marriages occurring in Canada are kept centrally at the Bureau of Statistics. From each of these microfilms, a punch-card, bearing a non-repetitive serial number and containing particulars of the event and of the individuals involved, is prepared as a matter of routine. At present a modification in the punching of these cards is under consideration. The modification is designed to enable each birth card to be identified mechanically with the marriage card of the parents, matching by name of father, maiden name of mother, and parents' initials and birth years; while the death cards would in a similar manner be identified with the individual's birth cards, matching by family name, first name and initials, province and date of birth. A small proportion of apparent discrepancies are known to arise, almost all of which could be matched manually.

The new birth and death cards would have additional blank spaces into which could be transferred the serial number from the corresponding marriage card. This operation would be mechanical, and the serial number from the marriage card would then become a "family number", enabling all three cards to be readily identified into family groups.

The change in the method of punching would not add appreciably to the present costs, which are in the vicinity of $100,000 per year, while the additional matching procedures and the punching of the family number might perhaps double these costs. This estimate refers to a proposed ten-year pilot study, but in a continuing study the handling of an expanding file of cards would involve a further increase in cost which has not as yet been estimated.

---

[8] Scottish Council for Research in Education (1949) Report of the * * *, London.

In addition, to identify all marriages between first counsins, the microfilms of the marriage registration forms would be scrutinized, and those in which one of the bride's parents had the same family name as one of the groom's parents would be singled out. In the case of these registrations (which amount to about 1%–2% of all marriages in Canada), the birth records of the bride and groom, and then of the respective parents of similar family name, would be checked for positive identification of the marriages which are in fact between first counsins. One man can scan approximately 1000 marriage registrations a day for this purpose, and searching of birth records is a function which the provinces carry out routinely at a relatively small cost.

When a Family Register Index is created, it would be used in conjunction with an Ill-health Register of all "affected" persons, who will be identifiable by their names and by the dates and places of their births, if they have not already been identified by the "family number". The latter register would include stillbirths, infant deaths, other deaths, congenital malformations, hospital records, other medical records, etc. From the two registers one would derive the sizes of the sibling groups and the numbers of affected individuals in each. Weinberg's propositus method would be used to calculate the probability that a sibling of an affected individual will be similarly affected: $p=\Sigma x(x-1)/\Sigma x(s-1)$, where p is the required probability, x the number of affected persons in the families, and s the number of children of the individual families. The incidence of the condition in offspring of first-counsin marriages, and in the population as a whole, would be obtained directly.

The Family Register Index can be thought of as a major research tool, designed to do away with the need for obtaining pedigrees by personal interview and thus to pave the way for whole-population studies of common diseases. Such studies would seem to be an integral part of any attempt to measure the practical consequences of genetic trends in terms of the general health of the population.

Details of Suggested 10-year Pilot Study

It has been proposed that before embarking on a major continuing programme of an entirely new kind, the design should be tested in a preliminary special study. In the present case there is an additional reason for such a study.

The main programme, if started solely with current registrations of marriages, and of the births and deaths of the children arising out of these, would require approximately four years before any comparisons could be made in brother-sister groups, and about ten years before it would have expanded sufficiently to yield data for a breakdown by cause of death. Only then would it be possible to evaluate the design of the project.

To avoid loss of time a special study could be carried out, essentially similar to the projected continuing study, but using existing records on a "backlog" basis. In drawing up the specifications it was assumed that the special study would cover the ten-year period from 1946 to 1955 inclusive. An attempt has been made to foresee the amount and kind of data which might be expected from the special study. It is estimated that there would be in the vicinity of a million infants born to the marriages under study, and that approximately half of these would have at least one brother or sister with whom comparisons could be made.

The special study would deal mainly with infant deaths, and should indicate the extent to which deaths from various causes tend to be correlated in families and in the offspring of first-counsin marriages. These correlations (i e., the factors by which the various causes are more common in these two groups of individuals than in the population as a whole) are the values which will be expected to change with changes in gene frequencies. The study would show how large these factors are for the various causes of death, together with the confidence limits, and would at the same time indicate any changes which should perhaps be made in the design of the continuing study.

In addition, since the relatives of affected individuals constitute a group in which the frequencies of the predisposing genes are, as it were, artificially increased, the results should give us a better appreciation of the practical consequences of an increase in the incidence of deleterious genes in the population as a whole.

The extensive Family Register Index, developed during the special study, would be used in the continuing study so that current births from much earlier marriages could be included from the start. This would ensure an appreciable annual yield of data without having to wait until the marriages occurring in the first year of the study had yielded two children.

FUTURE FACILITIES AND THEIR POTENTIALITIES

With the present punch-card equipment a storage problem would eventually develop. The family Register Index must contain three cards for each individual who has been born, married and died, and family groups of cards will have to be retained until the last of the brothers and sisters has died. Probably the equilibrium number of cards would be in the vicinity of three for each living member of the population. The obvious solution is a system of miniature cards, capable of being mechanically sorted and matched. If, in addition, these cards had an increased information capacity and could be handled more rapidly, the usefulness of the Family Register Index would be enormously increased.

One such system—the Kodak Minicard, which has been described by Tyler, Myers & Kuipers [8]—is in the process of development. (Details: card size, 32 mm by 16 mm; storage space required, 15 inches by 30 inches by 50 inches per 2 000 000 cards; digital information capacity, between five and six times that of the standard punch-cards, with room for a photographic image of the original registration form as well; handling speeds of 1800 cards per minute for sorting and selecting.) Such a medium could replace both the existing microfilm and the punch-cards, while taking approximately the same space as the microfilm alone.

The most important use for the additional information capacity would be in the identification of relatives more distance than brothers and sisters. The "family identity number" assigned at the time of marriage would be carried forward, not only to the children's birth and death cards, but to the children's marriage cards as well, and so on. The number of steps in this carryover would of course depend ultimately on the amount of digital information space allocated to ancestor-family numbers.

Let us assume, for example, that two generations of ancestor-family numbers are present on all cards (requiring, for 10-digit numbers, 60 out of the 420 spaces which will be available when the card contains a photographic image as well). Causes of death could then be compared in children, parents and grandparents, and in other relatives as remote as second cousins, using a single sorting and matching of death cards.

Another medium which might have applications is magnetic tape. (Information capacity, 100 characters per inch; handling speed for tabulation and other purposes, 15,000 characters per second.) Records from cards which had been suitably sorted in advance could be incorporated each year, together with the accumulated records of previous years, into a single master-tape, which would be revised annually. Assuming that such a tape contained records from 50 000 000 cards with 100 characters per card, it would require approximately 100 hours (not counting the changing of reels) to run the entire tape through a machine in order to tabulate the information in the required form.

In view of the rapid improvement in the designs of such equipment, the bulk of information to be processed, and the complexity of the operations involved, should not constitute more than a temporary limitation on any system of handling which was deemed necessary.

CONCLUSION

In this account it has been assumed that we may not be able to assess adequately the genetic damage occurring in irradiated human populations, either from a knowledge of the changes in mutation rates, or by observing the changes in fitness in similarly irradiated animal populations, or even by observing the prevalence of a number of genetically well-defined "indicator conditions". With each of these observations there remains an uncertainty as to the amount by which the ill-health of the population has been altered, and if the answer cannot be stated in such terms it is of only limited use.

This would seem to lead us to the much more arduous and exacting task of attempting to detect changes in the genetic factors which affect broad categories of human ill-health. The degree of precision which might be achieved is impossible to predict, but it is clear that we could not afford to waste any of the available information relating to the health of the individuals who make up the population, to their family relationships, or to the environments in which they have been reared.

Experience in effectively handling the masses of information of these three kinds which are at present readily available would seem to be one of our imme-

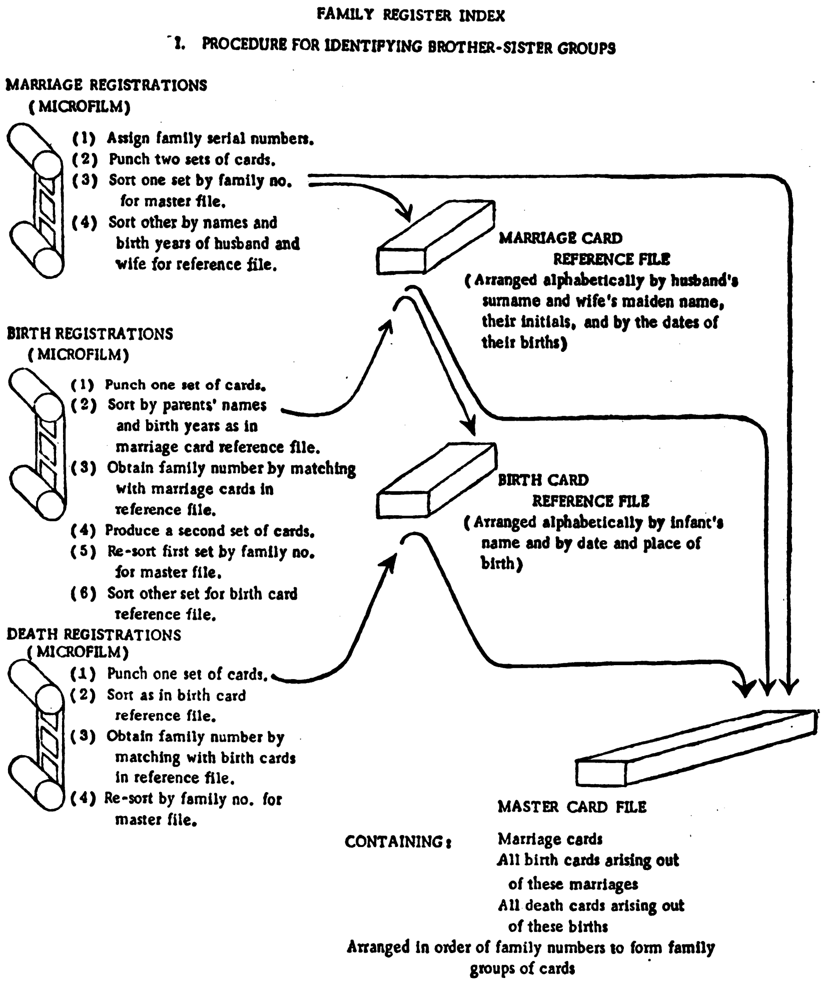
[8] Tyler, A. W., Myers, W. L., and Kuipers, J. W. (1955) Amer. Documentation, 6, 18.

diate needs, while improvement in the routine sources of information is another. It is with the first of these needs that the present paper has been primarily concerned.

ACKNOWLEDGMENTS

While the opinions expressed in this paper are entirely those of the writer, the procedures described are the outcome of numerous discussions with representatives of the Bureau of Statistics and the Department of National Health and Welfare, and with other geneticists. In the latter connexion, the writer would like to thank Mr Fraser Harris, Mr S. J. Axford, Mr Gordon H. Josie, Dr A. P. James and Dr F. Clarke Fraser for their generous co-operation.

FIG. 1. FAMILY REGISTER INDEX - 1



If both the family information and the vital statistics are included on a single card, tabulations from the Master Card File will yield family sizes and numbers of children "affected", from which sibling correlations can be derived. Note that with the use of a miniature card the storage space required for the Master Card File would be about the same as that needed for the microfilms of the corresponding registration forms.

FIG. 2. FAMILY REGISTER INDEX—II

FAMILY REGISTER INDEX

II. PROCEDURES FOR IDENTIFYING FIRST COUSIN MARRIAGES

A. Procedure to be used when family index is first started

(1) Examine all marriage registrations for cases in which a parent of the groom and a parent of the bride have the same surname (or maiden name).

(2) Where this is observed, search the birth records of the bride and groom for the birth years of the parents of similar name.

(3) Then, search the birth records of the parents of similar name. Where the bride and groom are first cousins the names of the common grandparents will be found on both registrations.

(4) Enter consanguinity on the marriage card in the family register index, and on all subsequent birth and death cards arising out of this marriage.

B. A more direct procedure using the family numbers assigned to the marriages in the two preceding generations (the method will be usable after the family register index has been in operation for about 40 years)

(1) Carry forward the following family serial numbers on to all new marriage cards:

(a) From the groom's parents' marriage
(b) From the bride's parents' marriage
(c) From the groom's paternal grandparents' marriage
(d) From the groom's maternal grandparents' marriage
(e) From the bride's paternal grandparents marriage
(f) From the bride's maternal grandparents' marriage

(2) Where the family number for (c) or (d) is the same as that for (e) or (f), the bride and groom are first cousins. Cards in which this is the case will be identified mechanically.

(3) Enter consanguinity on the marriage card, and on all subsequent birth and death cards arising out of the marriage.

The first of these procedures can be used immediately in the case of all provinces where the maiden names of the mothers of both bride and groom appear on the marriage registration form (i. e., all provinces in Canada except Quebec).

The second procedure will enable consanguinity data to be obtained from all of the provinces, after the Family Register Index has been in operation for a sufficient period.

APPENDIX 4

THE BIOLOGICAL EFFECTS OF ATOMIC RADIATION AND EXCERPTS FROM PATHOLOGIC EFFECTS OF ATOMIC RADIATION, STUDIES BY THE NATIONAL ACADEMY OF SCIENCES, NATIONAL RESEARCH COUNCIL

THE BIOLOGICAL EFFECTS OF ATOMIC RADIATION

SUMMARY REPORTS FROM A STUDY BY THE NATIONAL ACADEMY OF SCIENCES

National Academy of Sciences—National Research Council, Washington, 1956

FOREWORD

The reports published in this volume summarize the first technical findings and recommendations of six committees established to carry on a continuing study of the biological effects of atomic radiations from the points of view of

genetics, pathology, meteorology, oceanography and fisheries, agriculture and food supplies, and the disposal and dispersal of radioactive wastes.

The members of these committees, numbering more than 100, are among the most distinguished scientists in their fields in the United States. They have given generously of their time and talents in making this analysis during the past several months because they are convinced that their fellow citizens should have the facts about the biological effects of atomic radiations based on all existing knowledge available to us. The members of the committees served as individuals, contributing their knowledge and their judgment as scientists and as citizens, not as representatives of the institutions, companies, or Government agencies with which they are associated.

The use of atomic energy is perhaps one of the few major technological developments of the past 50 years in which careful consideration of the relationship of a new technology to the needs and welfare of human beings has kept pace with its development. Almost from the very beginning of the days of the Manhattan Project careful attention has been given to the biological and medical aspects of the subject. By contrast, the automobile revolutionized our pattern of living and working, but we are only now beginning to appreciate the problems of safety, urban congestion, nervous tension, and atmospheric pollution which have accompanied its development. In the same way, the development of the aircraft industry outran our knowledge of how to meet the environmental needs of the human beings it intended to transport through the skies.

The reports now completed vary greatly as to the extent of technical detail they contain. The full reports of each committee, including technical appendices where these have been prepared, will be published at a later date by the National Academy of Sciences. Here only the essential facts, arguments. and conclusions as seen today by each Committee are published. As further research provides new facts or further consideration sheds new light on what is now known these conclusions will almost certainly be modified. Moreover as time permits certain specialized aspects of the problem will be studies in more detail by the Committees. The results of these further analyses will be published from time to time as the National Academy of Sciences' study continues.

Douglas M. Whitaker, Vice President of the Rockefeller Institute, has provided coordination and liaison among the study committees with the assistance of Charles I. Campbell of the Academy staff. The study has been greatly assisted by consultations with many authorities in private and Government organizations. Particular mention should be made of the cooperation of the United States Atomic Energy Commission and the Department of Defense. Financial support of the Academy's study of the biological effects of atomic radiations is provided by the Rockefeller Foundation.

DETLEY W. BRONK,
President, National Academy of Sciences.

June 4, 1956.

MEMBERSHIP OF THE COMMITTEE ON GENETIC EFFECTS OF ATOMIC RADIATION

Warren Weaver, The Rockefeller Foundation, Chairman
H. Bentley Glass, Johns Hopkins University, Rapporteur
George W. Beadle, California Institute of Technology
James F. Crow, University of Wisconsin
M. Demerec, Department of Genetics, Carnegie Institution of Washington
G. Failla, Columbia University
Alexander Hollaender, Oak Ridge National Laboratory
Berwind P. Kaufmann, Department of Genetics, Carnegie Institution of Washington
C. C. Little, Roscoe B. Jackson Memorial Laboratory
H. J. Muller, Indiana University
James V. Neel, University of Michigan
W. L. Russell, Oak Ridge National Laboratory
T. M. Sonneborn, Indiana University
A. H. Sturtevant, California Institute of Technology
Shields Warren, New England Deaconess Hospital
Sewall Wright, University of Wisconsin
Consultants:
John S. Laughlin, Sloan-Kettering Institute
Ira Pullman, Nuclear Development Corporation of America

MEMBERSHIP OF THE COMMITTEE AND SUBCOMMITTEES ON PATHOLOGIC EFFECTS OF ATOMIC RADIATION

Committee Members:
- Shields Warren, New England Deaconess Hospital, Boston, Chairman
- Austin M. Brues, Argonne National Laboratory, Rapporteur
- Howard Andrews, National Institute of Health
- Harry Blair, School of Medicine, University of Rochester
- John C. Bugher, Rockefeller Foundation
- Eugene P. Cronkite, Brookhaven National Laboratory
- Charles E. Dunlap, School of Medicine, University of Tulane
- Jacob Furth, Children's Cancer Research Foundation, Boston
- Webb Haymaker, Armed Forces Institute of Pathology
- Louis H. Hempelmann, School of Medicine, University of Rochester
- Samuel P. Hicks, New England Deaconess Hospital, Boston
- Henry S. Kaplan, Stanford University Medical School, San Francisco
- Sidney Madden, School of Medicine, University of California at Los Angeles
- R. W. Wager, Hanford Atomic Products Operation, General Electric Company

Subcommittee on Acute and Long Term Hematological Effects:
- Eugene P. Cronkite, Brookhaven National Laboratory, Chairman
- Carl V. Moore, Washington University School of Medicine
- William N. Valentine, University of California Medical Center
- Victor P. Bond, Brookhaven National Laboratory
- William Moloney, Boston City Hospital
- George V. LeRoy, Billings Hospital, University of Chicago
- George Brecher, National Institutes of Health
- James S. Nickson, Memorial Hospital, New York
- Consultants:
  - James Hartgering, Lt. Col. (MC) USA
  - Karl Tessmer, Lt. Col. (MC) USA, Walter Reed Army Medical Research Institute

Subcommittee on Toxicity of Internal Emitters:
- Austin M. Brues, Argonne National Laboratory, Chairman
- Thomas F. Dougherty, University of Utah
- Miriam P. Finkel, Argonne National Laboratory
- H. L. Friedell, Western Reserve University
- Harry A. Kornberg, General Electric Company, Richland, Wash.
- Kermit Larson, University of California, Los Angeles
- Wright Langham, Los Alamos Scientific Laboratory
- Hermann Lisco, Argonne National Laboratory
- William P. Norris, Argonne National Laboratory
- J. Newell Stannard, University of Rochester
- Joseph D. Teresi, Naval Radiological Defense Laboratory
- Raymond E. Zirkle, University of Chicago
- Consultants:
  - R. J. Hasterlik, University of Chicago
  - L. D. Marinelli, Argonne National Laboratory
  - Jack Schubert, Argonne National Laboratory
  - Charles L. Dunham, U. S. Atomic Energy Commission

Subcommittee on Acute and Chronic Effects of Radioactive Particles on the Respiratory Tract:
- Ralph W. Wager, Hanford Atomic Products Operation, General Electric Co., Chairman
- Stanton H. Cohn, U. S. Naval Radiological Defense Laboratory
- John W. Heally, Hanford Atomic Products Operation, General Electric Company
  - Francis R. Holden, Stanford Research Institute
- James K. Scott, University of Rochester
- J. N. Stannard, University of Rochester
- George V. Taplin, University of California School of Medicine
- Consultants:
  - Averill A. Liebow, Yale University School of Medicine
  - C. C. Gamertsfelder, ANP Department, General Electric Co.

Subcommittee on Permanent and Delayed Biological Effects of Ionizing Radiations From External Sources:

Henry A. Blair, Department of Radiation Biology, Chairman
George W. Casarett, Department of Radiation Biology
Louis H. Hempelmann, Division of Experimental Radiology
John B. Hursh, Department of Radiation Biology
Marylou Ingram, Department of Radiation Biology
Thomas R. Noonan, Department of Radiation Biology
James K. Scott, Departments of Pharmacology and Pathology
Lawrence W. Tuttle, Department of Radiation Biology

All of the above personnel are members of the faculty of the University of Rochester School of Medicine and Dentistry, Rochester, New York.

MEMBERSHIP OF THE COMMITTEE ON METEOROLOGICAL ASPECTS OF THE EFFECTS OF ATOMIC RADIATIONS

Dr. Harry Wexler, U. S. Weather Bureau, Chairman
Dr. Lester Machta, U. S. Weather Bureau, Rapporteur
Colonel B. G. Holzman, Hdqtrs., Air Research and Development Command
Lt. Colonel N. M. Lulejian, Hdqtrs., Air Research and Development Command
Dr. H. G. Houghton, Massachusetts Institute of Technology
Dr. W. W. Kellogg, the RAND Corporation
Dr. Heinz Lettau, Air Force Cambridge Research Center
Mr. Merril Eisenbud, U. S. Atomic Energy Commission
Dr. R. R. Braham, Jr., Institute of Atmospheric Physics
Mr. Charles E. Anderson, Geophysics Research Directorate, Bedford, Massachusetts
Dr. William K. Widger, Geophysics Research Directorate, Bedford, Massachusetts
Mr. R. J. List, U. S. Weather Bureau
Mr. D. Lee Harris, U. S. Weather Bureau
Consultants:
Irving H. Blifford, Naval Research Laboratory
Joshua Z. Holland, U. S. Atomic Energy Commission
Donald H. Pack, U. S. Weather Bureau

MEMBERSHIP OF THE COMMITTEE ON OCEANOGRAPHY AND FISHERIES

Roger Revelle, Scripps Institution of Oceanography, Chairman
Howard Boroughs, University of Hawaii
Dayton E. Carritt, Johns Hopkins University
Walter A. Chipman, U. S. Department of the Interior, Fish and Wildlife Service
Harmon Craig, Scripps Institution of Oceanography
Lauren R. Donaldson, University of Washington
Richard H. Fleming, University of Washington
Richard F. Foster, General Electric Company, Richland, Washington
Edward D. Goldberg, Scripps Institution of Oceanography
John H. Harley, U. S. Atomic Energy Commission
Bostwick Ketchum, Woods Hole Oceanographic Institution
Louis A. Krumholz, American Museum of Natural History
Charles R. Renn, Johns Hopkins University
M. B. Schaeffer, Scripps Institution of Oceanography
Allyn C. Vine, Woods Hole Oceanographic Institution
Lional A. Walford, U. S. Department of the Interior, Fish and Wildlife Service
Warren S. Wooster, Scripps Institution of Oceanography
Consultants:
Theodore Folsom, Scripps Institution of Oceanography
Theodore Rice, U. S. Department of the Interior, Fish and Wildlife Service
George A. Rounsefell, U. S. Department of the Interior, Fish and Wildlife Service
Paul Thompson (Alternate for Dr. Walford), Fish and Wildlife Service

MEMBERSHIP OF THE COMMITTEE ON EFFECTS OF ATOMIC RADIATION ON AGRICULTURE AND FOOD SUPPLIES

A. G. Norman, University of Michigan, Chairman
C. L. Comar, Oak Ridge Institute of Nuclear Studies
George W. Irving, Jr., U. S. Department of Agriculture

James H. Jensen, Iowa State College
J. K. Loosli, Cornell University
Roy L. Lovvorn, North Carolina State College
Ralph B. March, University of California, Riverside
George L. McNew, Boyce Thompson Institute for Plant Research
Boy Overstreet, University of California, Berkeley
Kenneth B. Raper, University of Wisconsin
H. A. Rodenhiser, U. S. Department of Agriculture
W. Ralph Singleton, University of Virginia
Ralph G. H. Siu, Office of the Quartermaster General
G. Fred Somers, University of Delaware
George F. Stewart, University of California, Davis
Consultants:
A. J. Lehmann, Food and Drug Administration
Robert Somers, Meat Inspection Service, U. S. Department of Agriculture
J. Wolfe, U. S. Atomic Energy Commission

MEMBERSHIP OF THE COMMITTEE ON DISPOSAL AND DISPERSAL OF RADIOACTIVE WASTES

Abel Wolman, Johns Hopkins University, Chairman
J. A. Lieberman, U. S. Atomic Energy Commission, Rapporteur
F. L. Culler, Oak Ridge National Laboratory
A. E. Gorman, U. S. Atomic Energy Commission
L. P. Hatch, Brookhaven National Laboratory
H. H. Hess, Princeton University
C. W. Klassen, Illinois State Department of Public Health
Sidney Krasik, Westinghouse Atomic Power Division
H. M. Parker, General Electric Atomic Energy Project, Hanford
W. A. Patrick, Johns Hopkins University
S. T. Powell, Consulting Engineer, Baltimore
Leslie Silverman, Harvard University School of Public Health
Philip Sporn, American Gas and Electric Company, New York
Conrad P. Straub, Oak Ridge National Laboratory
C. V. Theis, U. S. Geological Survey
Forrest Western, U. S. Atomic Energy Commission
Consultants:
Paul C. Aebersold, U. S. Atomic Energy Commission
Karl Z. Morgan, Oak Ridge National Laboratory

REPORT OF THE COMMITTEE ON GENETIC EFFECTS OF ATOMIC RADIATION

FOREWORD

The National Academy of Sciences, with the approval of the top Government authorities, is carrying out an over-all Study of the Biological Effects of Atomic Radiations. One part of that general study is being made by a Genetics Committee, and the present report is a preliminary one from that Committee.

This Genetics Committee has sixteen members, whose names and positions are listed at the beginning of this report. Thirteen of these have been directly and extensively concerned with research in genetics. This number includes specialists on the genetics of lower forms of life, on the genetics of such mammals as mice, on the more mathematical aspects of population genetics, and on human genetics. One member is specially experienced in the general biological effects of radiation, one in radiological physics, and one in pathology.

The problems of the Atomic Age affect every man, woman, and child—in fact, every living thing—in our country, and of course in the whole world as well. Although many of these problems are technical in character, it is nevertheless of importance to our democracy that these matters be as widely understood as possible. Therefore every effort has been made that this report be generally understandable.

This necessitates a certain amount of explanation of technical matters; but this report will use just as few unfamiliar terms as possible, and will define those that are used. It should be understood that many of the statements made in this report would require various qualifications and a lot more detail to attain full technical precision.

The subject is an inherently complicated one, and the reader must be prepared for a certain amount of detailed explanation, some of which is not easy to grasp.

It is felt that the subject is important enough so that many citizens will wish to make the effort which is necessary to a careful reading of this report.

The simplifications and abbreviations which have been adopted in this report in order to achieve a generally understandable presentation will undoubtedly be recognized by, and it is hoped will not disturb, the more technical reader. The later sections of the present report will be supplemented by more detail and factual justification if this is later desired by any of the agencies (as for example, the National Committee on Radiation Protection, the Atomic Energy Commission, governmental and industrial groups concerned with radiation hazards, etc.), which have responsibility for the procedures and standards to which our recommendations apply.

This particular report is preliminary for two reasons. First, we wish later to make a fuller report with more technical detail. Second, the situation is changing at such a rate that there should be a continuing series of reports, each bringing the subject up to date.

The National Academy study is not directed toward the problems posed by wartime use of atomic weapons, nor toward the political aspects of atomic power. The study is only indirectly concerned with the social and economic aspects. In fact, the National Academy study, as its title indicates, is concerned with the *possible biological hazards* due to atomic and other radiations. And the present report, made by the Genetics Committee, is concerned with the *genetic aspects* of the possible biological hazards. As this report is read, it should become progressively clearer what these genetic aspects are.

(I) WHAT ARE WE WORRIED ABOUT?

The coming of the Atomic Age has brought both hopes and fears. The hopes center largely around two aspects: the future availability of vast resources of energy; and the benefits to be gained in biology, medicine, agriculture, and other fields through application of the experimental techniques of atomic physics (isotopes, beams of high-energy particles, etc.).

Gains in both of these areas can be of great benefit to mankind. Advances in medicine and agriculture are obviously desirable. The wide availability of power can also be of great benefit, if we use this power wisely. For not only should there be enough power to meet the more obvious and mechanical demands, there should be enough to affect society in much more far-reaching and advantageous ways, so as to reduce world tensions by raising the economic standards of areas with more limited resources.

On the other hand, the Atomic Age also brings fears. The major fear is that of an unspeakably devastating atomic war. Along with this is another fear, minor as compared with total destruction but nevertheless with grave implications. When atomic bombs are tested, radioactive material is formed and released into the atmosphere, to be carried by the winds and eventually to settle down at distances which may be very great. Since it does finally settle down it has aptly been named "fall-out."

There has been much concern, and a good deal of rather loose public debate, about this fall-out and its possible dangers.

Are we harming ourselves; and are there genetic effects which will harm our children, and their descendants, through this radioactive dust that has been settling down on all of us? Are things going to be still worse when presently we have a lot of atomic power plants, more laboratories experimenting with atomic fission and fusion, and perhaps more and bigger weapons testing? Are there similar risks, due to other sources of radiation, but brought to our attention by these atomic risks?

(II) WHAT COMPLICATIONS ARE MET IN REACHING A DECISION?

Now it is a plain fact, which will be explained in some detail later in this report, that radiations,[1] penetrating the bodies of human beings, are genetically undesirable. Even very small amounts of radiation unquestionably have the power to injure the hereditary materials. Ought we take steps at once to reduce, or at least to limit, the amount of radiation which people receive?

There are two major difficulties that make it very hard to decide what is sensible to do. First, although the science of genetics is as precise and as

[1] Throughout this report the word "radiation" is not used in its broadest sense, but refers to certain kinds of high-energy radiations which are described in Section V.

advanced as any part of biology, it has in general, and particularly in human genetics, not yet advanced far enough so that it is possible to give at this time precise and definite answers to the questions: just *how* undesirable, *how* dangerous are the various levels of radiation; just *what* unfortunate results would occur?

Second, even if the relevant questions concerning radiation genetics could be answered definitively that would be only part of the story. The over-all judgment (how much radiation should we have?) involves a weighing of values and a balance of opposing aims in regard to some of which the techniques of physical and biological science offer little help.

What is involved is not an elimination of all risks, for that is impossible—it is a balance of opposed risks and of different sorts of benefits. And in disturbing and confusing thing is that mankind has to seek to balance the scale, *when the risk on neither side is completely visible.* The scientists cannot say with exact precision just what biological risks are involved in various levels and sorts of radiation exposure (these considerations being on one pan of the risk-scale); nor can anyone precisely evaluate the over-all considerations of national economic strength, of defense, and of international relations (all on the other pan of the scale).

(III) MUST WE THEN MOVE ENTIRELY IN THE DARK?

Does this mean that geneticists have, at the moment, nothing useful to say on this grave subject? Fortunately, this is not the case. We do know something, though not nearly enough to give definite answers to a great many important questions. There is a considerable margin of uncertainty about much of this, and as a result, there are naturally some differences of opinion among geneticists themselves as to exact numerical values, *although no disagreement as to fundamental conclusions.*

Many people, moreover, suppose science to be definite—open or shut. Things are supposed to be so or not so. And, therefore, some persons may, quite mistakenly, conclude that geneticists are unscientific because they do not completely agree on all details.

In relatively simple fields, where both theory and experiment have progressed far, a comforting kind of precision does often obtain. But it is characteristic of the present state of human radiation genetics that one must carefully and painstakingly note a lot of qualifications, of special and sometimes very technical conditions, of cautious reservations. The public should recognize that the attitudes and statements of geneticists about this problem of radiation damage have resulted from deep concern and from attempts to exercise due caution in a situation that is in essence complicaed and is of such great social importance.

It is not surprising that our knowledge of genetics—and especially human radiation genetics—is so fragmentary. What goes on inside cells and the effects of radiations on these processes are extremely complicated and subtle problems. To attack them successfully requires a tremendous lot of time; for the inherent variability of certain of these effects is such that to establish something with certainty one must do not one experiment but many thousands of individual tests and observations. To attack these problems also requires a high degree of special skill—and perhaps most of all, imaginative ideas which can be tested.

Single-celled organisms, as well as fruit flies and corn plants, have been specially rewarding objects of genetic study. In evolutionary terms, however, insects and plants are clearly a long way from man, and we are really just beginning to get genetic information about the effects of radiation on some of the lower mammals, such as mice. Even so, several matters of profound importance have already become clear: bacteria or fruit fly, mouse or man, the chemical nature of the hereditary material is universally the same; the main pattern of hereditary transmission of traits is the same for all forms of life reproducing sexually; and the nature of the effects of high-energy radiations upon the genetic material is likewise universally the same in principle. Hence, when it comes to human genetics, where the impossibilities of ordinary scientific experimentation are clear and only a tantalizing start has been made, we can at least feel certain of the general nature of the effects, and need only to discover ways in which to measure them precisely.

(IV) HOW COULD WE REDUCE RADIATION RISK?

The major ways to reduce our present and future exposures to radiations would be: a) to reduce medical and other use of Xrays as much as is feasible; b) to

set and to observe regulations for the proper construction and the same operation of nuclear power plants and for the methods used to dispose of their radioactive wastes as well as the methods used in mining and processing the fissionable materials; c) to reduce the testing of atomic weapons and hence to reduce radioactive fall-out; d) to place limits on the human exposures involved in certain aspects of experimentation in atomic and nuclear physics.

To carry out the steps just mentioned would, in greater or lesser degree for the various items, reduce radiation risks. Progress with regard to step a) can doubtless be achieved, although to go too far in reducing the medical use of Xrays would of course lead to the risk of poorer diagnosis and less effective treatment of disease. But to carry out steps b), c), and d) would subject us to a different set of risks. We might thereby impede progress in the nuclear field. We might seriously weaken our country's position in the world. We might deny future generations some of the possible benefits of nuclear power and of other atomic discoveries.

(V) RADIOACTIVE MATERIAL AND RADIATIONS

Now that the problem has been posed, and now that we are warned somewhat about the difficulties, we must begin to consider some of the more technical issues involved. What is radioactive material, what are radiations, and what biological effects do they have?

By *radioactive material* is meant those naturally occurring substances such as radium, or those man-produced atoms resulting from atomic experiments, which are inherently unstable. Instead of remaining unchanged like ordinary atoms of familiar substances such as oxygen, gold, etc., the atoms of these radioactive substances act like alarm clocks set by mischievous gremlins for unknown times. Unpredictably (at least in individual instances, but predictably for the average behavior of a large number) these atomic alarm clocks "go off"; that is to say, they disintegrate.

When radio material disintegrates it emits, along with other less penetrating and hence less significant rays, certain high-energy rays known as gamma rays. Some of these rays are entirely similar to a beam of light, except for the important distinction that they readily penetrate human tissue which is nearly opaque to ordinary light. Also the energy of these rays is much higher than that of light, and this enables them to produce chemical and biological changes in the tissue they traverse. Rays of this sort, which transport energy from one point in space to some other point, are in general referred to as *radiation*. We also class as radiations beams of minute particles travelling at high speeds—such as electrons or neutrons which when they hit matter produce effects like those of the radiation mentioned.

As indicated above, gamma rays are emitted by naturally occurring radioactive substances, such as radium. They are also emitted by the radioactive materials which are produced in the nuclear fission which occurs in atomic weapons testing, in nuclear power installations, and in various sorts of experimental installations. These same rays, in dilute amounts, impinge on and penetrate all of us all the time. For radioactive material is, as an inevitable and hence normal procedure, built into the soil, rocks, plants, etc., and for that matter is also built into our own bodies. Similarly, such material exists on the luminous dials of our watches and clocks. The familiar Xrays of the hospitals and tuberculosis clinics, and in the offices of dermatologists and dentists, have properties of penetration and energy which are similar to gamma rays.

Throughout this report, the word "radiation" refers primarily to gamma rays and/or x-rays, sometimes to other sorts of radiations as will be more particularly mentioned later.

Everyone knows what a pound of beefsteak is, or a yard of cloth. We do not have that sort of familiarity with amounts, or units, or dosages of radiation. X or gamma radiation is measured in units called roentgens (abbreviated r; for example, "a dose of 3r"). Dental Xrays *involve* a dose (to the reproductive organs or gonads, that being the important matter from the point of view of genetics) of about 0.005 r; and a general fluoroscopic examination may involve a dose of 2r or even more.

(VI) SOME BASIC FACTS ABOUT GENETICS

Before we ask what effect radiations have on genetic processes, we must review a little basic information about genetics itself.

Every cell of a person's body contains a great collection, passed down from the parents, the parents' parents, and so on back, of diverse hereditary units

called *genes*. These genes singly and in combination control our inherited characteristics.

These genes, as was just stated, exist in every cell of the body. But from the genetic point of view the ordinary "body cells," which make up the body as a whole, are not comparably as important as the "germ cells" which exist in the reproductive organs, and which play the essential roles in the production of children.

The genes are strung together, single-file, to form tiny threads of genetic material called *chromosomes*, which are visible under a microscope. These chromosomes, in ordinary body cells, customarily exist as similar but not identical pairs. Human body cells normally contain 48 chromosomes, these constituting two similar but not identical sets of 24 chromosomes each. One of these sets of 24 chromosomes was inherited from the mother, for the egg cell carries a set of 24 chromosomes; and the other set of 24 chromosomes was inherited from the father, for the sperm cell also carries a set of 24.

All the genes that a person starts out with when the original egg cell is fertilized are in general kept unchanged as the cells divide and the person's body is elaborated and maintained. The process by which the dividing cells duplicate the genes may not always produce perfect copies, but it does so in general. But genes do nevertheless essentially change. They are changed by certain agents, notably by heat, by some chemical, and *by radiation*. It is with the last of these three agents of gene change that we are concerned in this report.

When a gene becomes permanently altered, we say it *mutates*. The gene in its altered form is then duplicated in each subsequent cell division. If the mutant gene is in an ordinary body cell, then it is merely passed along to other body cells; but the mutant gene, under these circumstances, is not passed on to progeny, and the effect of the mutant gene is limited to the person in whom the mutation occurred.

However, it cannot safely be assumed that the effect is a negligible one on the person in whom the mutation occurred, nor can it properly be said that this effect is nongenetic, even though passage to offspring is not involved. For various kinds of cellular abnormalities are known to be perpetuated within an individual through body-cell divisions; so these effects are genetic in the broad sense.

What is involved here is not only mutant genes, but also larger scale disruption of the genetic material, such as breakage of chromosomes.

The quantitative relations are not yet clear, but it is established that certain malignancies such as leukemia, and certain other cellular abnormalities can be induced by ionizing radiations. There is also some evidence that effects of this sort measurably reduce the life expectancy of the individual receiving the radiation. These risks have genetic aspects and therefore should receive mention in this report. Indeed these direct risks to the individuals exposed may well constitute another adequate genetic reason for limiting radiation exposures to the lowest practicable levels.

To return to a consideration of the risks which are passed on to progeny, the mutant gene may exist in a sperm or an egg cell as a result of a mutation having occurred either in that cell or at some earlier cell stage. In this case, a child resulting from this sperm or egg will inherit the mutant gene.

If we were to take the two chromosomes of a similar pair, stretch them out straight, and put them alongside each other, then each gene of one would be opposite a corresponding gene in the other. Thus the genes exist in pairs, as do the chromosomes. The two members of each pair of genes are not always identically the same. That is, in fact, why we call the chromosome pairs *similar* rather than *identical*. The two genes of a corresponding pair play similar roles, in that they both affect or help to determine the same characteristic of the whole organism. But one of the two may have a somewhat different, or a much more powerful effect than the other.

Thus of a certain pair of genes, both might be concerned with hair color. If both genes of this hair-color pair are the sort which favor red hair, then the person has red hair. If both genes are the sort which favor non-red hair (black, brown, or blond) then the person has non-red hair. But suppose that, of this pair of hair-color genes, one favors red hair and the other non-red hair. What happens then?

The answer (husbands and wives will understand this) is that one of the two usually dominates the situation and gets its way, although (and again this seems reasonable) the meeker one of the two usually manages to avoid being completely ignored.

Thus with one non-red gene (this being the powerful and dominant one of the two), and one red gene (this being the meeker one), the hair is ordinarily not red, but the red gene may nevertheless produce some effect, a little red showing in the hair so as to make it faintly rusty or tawny in color.[8]

The powerful type of gene, which gets all or most of its own way in contrast to its companion gene, is very naturally called a *dominant* gene. The less effective type is called a *recessive* gene. In this same terminology, non-red hair color is called a *dominant characteristic*, whereas red hair color is called a *recessive characteristic*. A recessive characteristic actually fully appears only if both of the relevant genes are of the recessive type. Of great importance for our present study is the fact that *mutant genes*—genes which have, for example, been changed by radiations—*are usually of the recessive type.*

It is now easy to see that any organism may have, latent in its genetic constitution, ineffectual or recessive genes that have not had much of a chance to become apparent in its developed external characteristics, since the recessive genes are masked by their dominant companion genes. Yet often, as we have seen, this dominance is incomplete and recessive gene is able to manifest itself partially.

When the two genes of a pair are alike (both recessive or both dominant) then they are called a *homozygous* pair; but when one is recessive and the other dominant, then the pair is called *heterozygous*. Thus a recessive characteristic (like red hair) can be fully expressed only when the corresponding gene pair is homozygous.

(VII) RADIATIONS AND GENETIC MUTATIONS

We are now in a position to indicate why it is that radiations, such as X-rays or gamma rays, can be so serious from the genetic point of view. For although the genes, as described above, normally remain unchanged as they multiply and are passed on from generation to generation, they do very rarely change, or *mutate;* and *radiation*, as we have already mentioned, *can give rise to such changes or mutations in the genes.* The change is presumably an alteration in the complicated chemical nature of the gene, and the energy furnished by the radiation is what produces the chemical change. Mutation ordinarily affects each gene independently; and once changed, an altered gene then persists from generation to generation in its new or mutant form.

Moreover, the mutant genes, in the vast majority of cases, and in all the species so far studied, lead to some kind of harmful effect. In extreme cases the harmful effect is death itself, or loss of the ability to produce offspring, or some other serious abnormality. What in a way is of even greater ultimate importance, since they affect so many more persons, are those cases that involve much smaller handicaps, which might tend to shorten life, reduce number of children, or be otherwise detrimental.

The changed character, due to the mutated gene, seldom appears fully expressed in the first generation of offspring of the person who received the radiation and thus had one of his genes mutated. For these mutant genes are usually recessive. If a child gets from one parent a mutant gene, but from the other parent a normal gene belonging to that pair, then the normal gene is very likely to be at least partially dominant, so that the normal characteristic will appear.

But this is not all of the story. For, like the red-hair gene, the harmful recessive mutant genes are not usually completely masked. Even when paired with a normal and dominant gene, that is to say even when in the heterozygous state, they still have some detrimental effect. This "heterozygous damage" is ordinarily much smaller than the full expression of the mutant when in the homozygous state, and yet there may be a significant shortening of the length of life or reduction of the fertility of the heterozygous carriers of the mutant. And the risk of heterozygous damage *applies to many more individuals*, indeed to every single descendant who receives the gene.

The relations of genes to ordinary traits (not to the most simply determined biochemical traits (are of course much more complex than the previous paragraph would seem to imply. Such gene-determined traits may vary from person to person, due perhaps to environmental differences, and often may not even appear at all. A single gene usually affects several such characters, and char-

[8] The accurate and complete genetic story about red hair is more complicated than has been stated here. There are less familiar characteristics—thalassemia and sickle cell anemia for example—which more strictly conform to the simple pattern here described.

acters are practically always affected by many genes. Also the effect of a gene may depend on what other genes are present, often in a complex way. For example, a mutation tending to increase weight might be harmful to certain persons, but beneficial to others.

Indeed it is likely that a large fraction of the genes that determine normal variability are of this rather ambiguous type that are sometimes deleterious, sometimes not. Mutations within this sort would not necessarily be harmful. Such mutations presumably occur, but geneticists do not know what fraction of all mutations are of this type, for they are not ordinarily detectable. However, the mutations that form the basis of this report are those that are relatively detectable, and these, as mentioned earlier, are almost always harmful.

Individuals bearing harmful mutations are handicapped relative to the rest of the population in the following ways: they tend to have fewer children, or to die earlier. And hence such genes are eventually eliminated—soon if they do great harm, more slowly if only slightly harmful. A mildly deleterious gene may eventually do just as much total damage as a grossly and abruptly harmful one, since the milder mutant persists longer and has a chance to harm more people.

In assessing the harm done to a population by deleterious genes, it is clear that society would ordinarily consider the death of an early embryo to be of much less consequence than that of a child or young adult. Similarly a mutation that decreases the life expectancy by a few months is clearly less to be feared than one that in addition causes its bearer severe pain, unhappiness, or illness throughout his life. Perhaps most obviously tangible are the instances, even though they be relatively uncommon in which a child is born with some tragic handicap of genetic origin.

A discussion of genetic damage necessarily involves, on the one hand, certain tangible and imminent dangers, certain tragedies which might occur to our own children or grandchildren; and on the other hand certain more remote trouble that may be experienced by very large numbers of persons in the far distant future.

No two persons are likely to weigh exactly alike these two sorts of danger. How does one compare the present fact of a seriously handicapped child with the possibility that large numbers of persons may experience much more minor handicaps, a hundred or more generations from now?

There are thoughtful and sensitive persons who think that our present society should try to meet its more immediate problems, and not worry too much about the long-range future. This viewpoint is in some instances supported by the belief that new ways, perhaps unimaginable at the moment, are likely eventually to be found for meeting problems.

There are other thoughtful and conscientious persons who think that we are specifically responsible for guarding, as well as we can now determine, the long future.

Recognizing the inevitability and propriety of both viewpoints, and recognizing that they lead different persons to express their concerns through different examples and with differing emphases, the fact of major importance for this present study is that, travelling by different routes, different geneticists arrive at the same conclusion: *Complexities notwithstanding, the genetic damage done, however felt and however measured, is roughly proportional to the total mutation rate.*

(VIII) MUTANT GENES AND EVOLUTION

Many will be puzzled about the statement that practically all known mutant genes are harmful. For mutations are a necessary part of the process of evolution. How can a good effect—evolution to higher forms of life—result from mutations practically all of which are harmful?

First of all, it is not mutations which, of themselves, produce evolution, but rather the action of natural selection on whatever combinations of genes occur. Much of evolutionary progress probably depends on changes within the range of normal variability, and thus depends on genes of very small effect, and of the type mentioned in the previous section which are favorable or unfavorable depending on what other genes are present. Thus evolution consists of a complex shifting of frequencies of such genes, accompanied by the continuous process of elimination of detrimental mutations and the occasional incorporation into the population of a favorable mutation.

Nature had to be rather ruthless about this process. Many thousands of unfortunate mutations, with their resulting handicaps, were tolerated, just so

long as an advantageous mutation could be utilized, once in a long while, for inching the race up slightly higher to a better adjustment to the existing conditions. The rare creature with an advantageous combination of genes was better fitted to survive and displace his less favored companions, and thus evolution was served, even though there were thousands of tragedies for every success.

The reader may be troubled by a second difficulty. If mutation results in at least some favorable types, and if these are building blocks of evolution, why is an increase in mutation rate regarded as undesirable? Why wouldn't an increase in mutation rate produce a larger total number of the favorable types and so speed up evolution? If the favorable types are normally quite rare, wouldn't it almost seem that increasing the mutation rate would be desirable? The answer to this question lies in the consideration that the bad effects of mutation must be balanced against the good. Some mutation is necessary for evolution, but if the mutation rate is too high, the unfavorable mutations will be so numerous that the species and its future evolution will be handicapped. Under present-day conditions of living and medical care, it seems unlikely that the unfavorable results of mutation are being eliminated nearly as rapidly as was formerly the case. In other words, one of the consequences of the amazing mastery of his environment which man has achieved has been an actual decrease in the severity of natural selection.

Geneticists in fact believe that although favorable mutations are rare compared with unfavorable ones, the human population probably already has, and will continue to have as a result of its present mutation rate and without additional mutations from increased radiation, a large enough total supply of favorable, partially favorable, and potentially favorable mutations. In other words, with our present mutation rate we shall continue to have a degree of genetic variability adequate for further evolution.

(IX) WHAT, THEN, CAN GENETICISTS SAY TO HELP RESOLVE OUR PROBLEM?

With the background furnished by the preceding discussion, we can now state rather concisely certain main points on which geneticists are in substantial agreement. Some of these points will partially repeat statements already made, but they are included here in order that this section be reasonably complete of itself.

(1) Radiations cause mutations.

Mutations affect those hereditary traits which a person passes on to his children and to subsequent generations.

(2) Practically all radiation-induced mutations which have effects large enough to be detected are harmful.

A small but not negligible part of this harm would appear in the first generation of the offspring of the person who received the radiation. Most of the harm, however, would remain unnoticed, for a shorter or longer time, in the genetic constitution of the successive generations of offspring. But the harm would persist, and some of it would be expressed in each generation. On the average, a detrimental mutation, no matter how small its harmful effect, will in the long run tip the scales against some descendant who carries this mutation, causing his premature death or his failure to produce the normal number of offspring.

Although many mutations do disturb normal embryonic growth, it is not correct that all, or even that most mutations, commonly result in monstrosities or freaks. In fact, the commonest mutations are those with the smallest direct effect on any one generation—the slight detrimentals.

(3) Any radiation dose, however small, can induce some mutations. There is no minimum amount of radiation dose, that is, which must be exceeded before any harmful mutations occur.

(4) For every living thing—bacterium, fruit fly, corn plant, mouse, or man—there exist mutations which arise from natural causes (cosmic rays, naturally occurring radiations from radium and similar substances, and also from heat and certain chemicals). These naturally occurring, and hence unavoidable, mutations are usually called "spontaneous mutations."

Like radiation-induced mutations, nearly all spontaneous mutations with detectable effects are harmful. Hence these mutations tend to eliminate themselves from the population through the handicaps or the tragedies which occur because the persons bearing these mutants are not ideally fitted to survive.

We all carry a supply of these spontaneous mutant genes. The size of

this supply represents a balance between the tendency of mutant genes to eliminate themselves, and the tendency of new mutants to be constantly produced through natural causes.

(5) Additional radiation (that is, radiation over and above the irreducible minimum due to natural causes) produces additional mutations (over and above the spontaneous mutations). The probable number of additional induced mutations occurring in an individual over a period of time is by and large proportional to the total dose of extra radiation received, over that period, by the reproductive organs where the germ cells are formed and stored. To the best of our present knowledge, if we increase the radiation by X%, the gene mutations caused by radiation will also be increased by X%.

The *total dose* of radiation is what counts, this statement being based on the fact that the genetic damage done by radiation is *cumulative*.

A larger amount of radiation produces a larger number of mutations. But within the limits of the radiation doses being considered in this report there is every reason to expect that these additional mutants would be of the same general sort as those produced by the natural background radiation. That is to say, mildly larger doses of radiation would produce *more*, but not *worse*, mutants.

(6) From the above five statements a very important conclusion results. It has sometimes been thought that there may be a *rate* (say, so much per week) at which a person can receive radiation with reasonable safety as regards certain types of direct damage to his own person. But the concept of a *safe rate* of radiation simply does not make sense if one is concerned with genetic damage to future generations. What counts, from the point of view of genetic damage, is not the rate; it is the *total accumulated dose to the reproductive cells of the individual from the beginning of his life up to the time the child is conceived.*

What is genetically important to a child is the total radiation dose that child's parents have received from their conception to the conception of the child. Since this report necessarily deals with averages, the significant total dose period should be, at least approximately, the number of years that normally elapses from the conception of a person to the average time at which offspring are conceived. In the United States, based on 1950 data, the average age of fathers at the births of all children is 30.5 years, whereas the average age of both parents is 28.0 years. It therefore seems sensible for us to use the round figure of 30 years, especially since this figure is the one usually chosen to measure a generation. Using this 30-year figure for characterizing the "total reproductive life radiation dose" would have the result that about half of the total offspring would receive the possible effects of a smaller, and about half the possible effects of a larger, radiation dose.

(7) The problems of defining and estimating genetic damage are very difficult ones.

There are at least three different aspects which must be considered. The first aspect places emphasis on the risk to the direct offspring and later descendants of those persons who, from occupational hazard or otherwise, receive a radiation dose substantially greater than the average received by the population as a whole.

The second aspect refers to the effect of the *average* dose on the population as a whole.

The third aspect refers in still broader terms to the possibility that increased and prolonged radiation might so raise the death rate and so lower the birth rate that the population, considered as a whole, would decline and eventually perish. We are at present extremely uncertain as to the level of this fatal threshold for a human population. This is one reason why we must be cautious about increasing the total amount of radiation to which the entire population is exposed.

These three approaches to the problem of genetic damage involve estimating the damage in successive generations and also the total damage in all generations, due to an increase in the amount of mutation. The relative emphasis one places on these three aspects depends in part on whether one thinks primarily in terms of distress to individual persons, or whether one thinks in terms of the population as a whole. Necessarily involved is the contrast between manifest harm to a few, and less evident but no less unreal harm to many. Also involved is the contrast between a more short-term and a more long-range point of view.

One way of thinking about this problem of genetic damage is to assume that all kinds of mutations on the average produce equivalent damage, whether as

a drastic effect on one individual who leaves no descendants because of this damage, or a wider effect on many. Under this view, the total damage is measured by the number of mutations induced by a given increase in radiation, this number to be multiplied in one's mind by the average damage from a typical mutation.

Measuring total damage in terms of the number of mutations does indeed necessarily involve this concept of the average damage from a typical mutation, and some geneticists find this concept difficult and illusive. They would point out that mutations may be grouped in classes that differ, on a subjective scale, many thousand-fold in the amount of damage per mutation. As examples they would cite a mutation which results in very early death of an embryo (which might cause very little social or personal distress), and a mutation which results in severe malformation to a surviving child (which would cause very great personal distress and which clearly involves a social burden).

Rather than utilizing this concept of the average total damage per mutation, some geneticists prefer to start with a consideration of the tangible damage which occurs now, as a result of the current rate of mutation and get an index of damage by multiplying this by the ratio of the expected new mutation rate to the current one. This procedure, however, admittedly deals with only *part* of the total damage; so an alternative difficulty faces those who prefer this procedure, namely the difficulty of estimating what part of the total damage they have dealt with.

As an illustration of the first aspect, suppose that ten thousand individuals were exposed to a large dose of radiation, of the order of 200 r. Then perhaps one hundred of the children of these exposed individuals would be substantially handicapped, this being in addition to the number handicapped from other causes. In this case the connection with the radiation exposure could be established by a statistical study.

As an illustration of the second aspect, suppose the whole population of the United States received a small dose of extra radiation, say 1 r. Then there is good reason to think that, among a hundred million children born to these exposed parents, there would be several thousand who would be definitely handicapped because of the mutant genes due to the radiation. But these several thousand handicapped children might be, so to speak, lost in the crowd. Society might be more impressed by the one hundred more obvious cases of the preceding paragraph than by the more hidden several thousand cases of this paragraph.

We should not disregard a danger simply because we cannot measure it accurately, nor underestimate it simply because it has aspects which appeal in differing degrees to different persons. Two conclusions seem to be clear and of importance: We should proceed with due caution as regards all agents which cause mutations; and we should vigorously pursue the researches which will in time give us a more precise way of judging all aspects of the risk.

(X) SOME REMARKS ABOUT APPROXIMATE ESTIMATES

Up to this point of the discussion the conclusions of the geneticist are pretty clear; the mutant genes induced by radiation are generally harmful, and the harm cannot be escaped.

But as yet this report has not furnished much of a basis for converting these conclusions into practical advice. Remembering that we must eventually balance risk against risk, it is obviously desirable to try to learn, as definitely as circumstances permit, the answer to the question: *how* great would be the genetic harm done by various doses of radiation?

Section XII of this report will respond to this question. But before giving the various replies, there should be some preliminary explanation concerning the nature of the answers given.

Science, and particularly the branch which deals with the physical world about us, has succeeded in giving highly precise answers to many questions. When one talks about the velocity of light he does not need to say that it is *something* like three hundred thousand kilometers per second: he is justified in saying that it *is* 299,793 km. per second, and that the final integer is almost certainly not off by more than two units.

But when you ask an experienced surgeon what your chances are of surviving a serious operation, and if he answers "something like nine chances out of

ten," then you accept that as a reasonable and helpful estimate. You do not distrust him because he gives you a rought estimate. Indeed you would have good cause to distrust him if he tried to give a highly precise answer.

In other words, there are many situations in which science can give only rough estimates. These estimates can nevertheless be very useful. No one should disdain such an estimate because it is rough, nor should anyone consider such estimates unscientific.

In Section XII there will be stated the results of certain approximate calculations. The theory behind these calculations is on the whole well understood; but it is seldom the case that one knows with much accuracy the numerical values that enter into the calculations. One may, for example, say, "I don't know, in any direct measured sense, how many mutants would result if all the genes in a human fertilized cell received one roentgen of radiation. But using a pretty definitely known value for the mutation rate in certain genes of the mouse; and also knowing fairly well (in this case from experiments with fruit flies) how to pass from the measured rate for a few genes to the rate which probably applies to a germ cell as a whole; and then making the unfortunate but necessary assumption that these mouse and fruit fly figures apply reasonably well to man—using this procedure I come out with estimates for the number of mutants which would be produced in man by a given dose of radiation. Because of the uncertainties, I think it prudent to state not a single final result, but rather a range of result with estimated lower and upper limits. I wish that we had direct experimental evidence which would firm up this estimate. But I don't have to be too apologetic, for a large amount of biological reasoning has been successfully based on this sort of procedure. Man differs widely from lower forms of life in all the obvious, and in many other, respects. But the fundamental processes inside cells tend to be curiously alike, from the simplest creature of a single cell, up to man."

It may turn out that the uncertainties in the quantities which enter the calculation are so great that the resulting uncertainty in the final answer is itself so very broad that the calculation simply does not furnish a useful estimate. But it may also turn out that, despite some considerable uncertainty in the constituent factors, the answer can be stated with a range of uncertainty which is small enough so that the estimate is useful.

It seems necessary to emphasize this matter of approximate estimation, so that no one will improperly conclude that a statement is unreliable because it involves a range of values. On the contrary, such a statement, when made in a situation like the present one, should be viewed as all the more dependable precisely because it does not pretend to an unwarranted accuracy.

(XI) HOW MUCH RADIATION ARE WE NOW RECEIVING?

If we are to talk about how harmful certain radiation doses may be, we should gain some idea of the amount of radiation we are already receiving from various sources.

The Committee will release a report specially devoted to this particular subject, which summarizes in detail all the kinds, sources, and amounts of radiation. In the present report, only that minimum amount of information will be given which is necessary for our current discussion.

Neglecting several minor contributions (all of which will be treated in the longer report), man is at present receiving radiations from the following:

(1) *Background Radiation*

This is the radiation which results from natural causes (cosmic rays, naturally occurring radium, etc.) not under our control. Each person receives on the average a total accumulated dose of about 4.3 roentgens over a 30 year period. At high altitudes this dose is greater, because of the increase of cosmic rays. Thus this background is as high as 5.5 r in some places in the United States.

(2) *Medical X Rays*

According to present estimates, each person in the United States receives, on the average, a total accumulated dose to the gonads which is about 3 roentgens of X-radiation during a 30 year period. Of course, some persons get none at all; others may get a good deal more.

(3) *Fall-out from Weapons Testing*

The Atomic Energy Commission[8] is doing a technically competent and a socially conscientious job of measuring fall-out: but it does not follow from this that one can answer, with high precision, all questions about the biological risks involved. What they usually measure (which, technically speaking, is a beta-ray activity in air) has to be translated over into what is genetically important (namely, the gamma ray dose to the gonads). The estimation of the latter of these quantities from the former is a pretty complicated business.

Besides those just mentioned, there are certain further uncertainties in the fall-out values. The measurements are necessarily taken far apart, and there is known to be considerable local variation due to meteorological conditions and topography. The radioactive dust, when it settles out of the air, is subject to weathering, as when it is washed off of buildings by the rain and carried to locations where it may affect fewer persons. Also individuals inside houses, or other shelters, will be considerably less exposed than those in the open air

Thus one cannot expect the figures on fall-out to be very precise ones. We have been informed that the AEC scientists are confident that the actual true dose figures are less than five times their stated estimates, and are also greater than one-fifth of these stated estimates.

It should be noted that the figures on fall-out as stated by the Atomic Energy Commission make only a conservative correction for weathering and shelter; and thus their figures, at least in regard to this point, tend to overstate the danger rather than the opposite.

With these understandings, it may be stated that U. S. residents have, on the average, been receiving from fall-out over the past five years a dose which, if weapons testing were continued at the same rate, is estimated to produce a total 30-year dose of about *one tenth of a roentgen;* and since the accuracy involved is probably not better than a factor of five, one could better say that the 30-year dose from weapons testing if maintained at the past level would probably be larger than 0.02 roentgens and smaller than 0.50 roentgens.

The rate of fall-out over the past five years has not been uniform. If weapons testing were, in the future, continued at the largest rate which has so far occurred (in 1953 and 1955) then the 30-year fall-out dose would be about twice that stated above. The dose from fall-out is roughly proportional to the number of equal sized weapons exploded in air, so that a doubling of the test rate might be expected to double the fall-out.

The figures just stated are based on all information now available from both the Atomic Energy Commission and the Armed Forces, and have been estimated as part of a study carried out for this Committee by Dr. John S. Laughlin, Chief of the Division of Physics and Biophysics, Sloan-Kettering Institute, and Dr. Ira Pullman, loaned to this study by the Nuclear Development Corporation of America. In their estimation correction has been made for weathering and shelter effects in accordance with the latest experimental data.

(4) *Atomic Power Plants*

As yet the general population has not received radiation from atomic power plants or from the disposal of radioactive wastes. These are future sources of radiation that might become dangerous.

(5) *Occupational Hazards*

The preceding four points apply to everyone. Unless proper precautions are taken, persons who are close to equipment emitting X rays who are engaged in experimental work in atomic energy, who operate atomic plants, who test weapons, who mine or otherwise handle radioactive material, etc., are subject to the risk of greater radiation exposure during their work.

(XII) HOW HARMFUL ARE RADIATION-INDUCED MUTATIONS?

As has already been indicated, there are various ways of estimating genetic harm, various attitudes which can be taken as to what is most serious and significant. But this situation should not be allowed to confuse or conceal the massive fact that, by whatever chain of argument or reasoning, all geneticists come out with the same basic conclusions.

[8] Under the Department of Defense other measurements, relating to fall-out, are also being made.

(A) Thus the first and unanimous reply to the question posed by the title to this section is simply this: *Any radiation is genetically undesirable*, since any radiation induces harmful mutations. Further, all presently available scientific information leads to the conclusion that *the genetic harm is proportional to the total dose* (that is, the toal accumulated dose to the reproductive cells from the conception of the parents to the conception of the child). This tells us that a radiation dose of 2X must be presumed to be twice as harmful as a radiation dose of X; but it still doesn't tell us the amount of harm we would be doubling.

(B) Second, we remember that mankind has for ages been experiencing, as the so-called spontaneous mutations, a certain rate of (generally harmful) mutations due to natural and uncontrolled causes (cosmic rays, heat, chemicals, etc.). It is not entirely unnatural to think of this burden of mutations as a sort of "normal" burden on society.[4] Therefore it seems to be illuminating to ask: how much additional "man-made" radiation will it take before this "natural" amount of genetic mutation (to which we are at least in some senses adjusted) will be doubled?

The calculations which lead to an estimate of this "doubling dose" necessarily involve the rates of both spontaneous and radiation-induced mutations in man. Neither of these rates has been directly measured; and the best one can do is to use the excellent information on such lower forms as fruit flies, the emerging information for mice, the few sparse data we have for man—and then use the kind of biological judgment which has, after all, been so generally successful in interrelating the properties of forms of life which superficially appear so unlike but which turn out to be so remarkably similar in their basic aspects.

In view of the inevitable uncertainties, it is rather surprising that the final estimates, as made by numerous specialists of this Committee and in other countries, do not differ more than they do. The lowest figure which has been responsibly brought forward for the doubling dose is 5 r, and the largest estimates range up to 150 r or even higher. Recent work with mice (which are, after all, mammals) gives some basis for thinking that the doubling dose is not as high as 150 r. The experience in Japan gives some basis for thinking that the doubling dose is larger than 5 r. Indeed it is clear that the doubling dose must be at least as large as the background radiation (which is between 4 and 5 r, over 30 years, in the United States). This, in fact, would be the value of the doubling dose if spontaneous mutations were due to background radiation alone, heat and chemical agents making no contribution.

Thus various arguments reduce the 5–150 r range, and several experienced geneticists have recently made estimates in the narrower range of 30 r to 80 r.

In summary then of this particular point: Each individual, on the average inevitably experiences during his reproductive lifetime a certain number of harmful spontaneous mutations from natural causes. He would experience an additional *equal number* of harmful mutations if he received a certain dose of radiation during that same period. This is known as the "doubling dose." The actual value of the doubling dose is almost surely more than 5 r and less than 150 r. It may very well be from 30 r to 80 r.

The first portion of this (Section XII) said that twice as much radiation gives twice as much harm. This second portion goes a bit further. It says that something like 30 r to 80 r (or at a further extreme, 5 r to 150 r) of extra radiation dose would do mankind twice the harm it is now experiencing from spontaneous mutations.

(C) The two preceding portions of this Section are clearly not really satisfying. They do indicate in quantitative terms how increases in radiation increase the harm. But anyone still wants to know in more specific terms, if possible, *how serious* is this harm that we may be doubling. If city traffic increases until the risk of crossing the street is doubled, then we will presumably still cross the street; for the risk per crossing is, after all, a very small one. If highway traffic increases until the risk in taking a thousand-mile drive is doubled, then many persons might well hesitate, for the risk is now unpleasantly high.

And this is the point at which it becomes most clearly evident that different geneticists find meaningful rather different approaches to the problem of genetic damage.

As has been stated previously, from one point of view the best index of genetic damage is the totality of tangible genetic defects of living individuals—

[4] There is some basis for hoping that we may eventually be able to control at least a part of both spontaneous and radiation-induced mutations.

say such things as mental defects, epilepsy, congenital malformations, neuromuscular defects, hematological and endocrine defects, defects in vision or hearing, cutaneous and skeletal defects, or defects in the gastro-intestinal or genitourinary tracts. Roughly 4–5% of all live births in the United States have defects of this sort; and of all of these, perhaps about half—or 2% of the total live births—have simple genetic origin and appear prior to sexual maturity.

If mankind were subjected to a "doubling dose" of radiation, then the present level of 2% of such genetic defects would rise, and would eventually be doubled. More explicitly, consider the next one hundred million births in the United States. This is about the number of children that will, in the future, be born to the presently alive population of the United States. Of these 100,000,000 children, something like 2,000,000 will experience genetic defects of the sort listed, these resulting from the deleterious "spontaneous" mutant genes which have been induced by natural causes excluding man-made radiation. If we were to be subjected, generation after generation, to an additional doubling dose of man-made radiation, then this present tragic figure of 2,000,000 would gradually increase by 2,000,000 more cases, up to an eventual new total of 4,000,000. It would, to be sure, take a very long time to reach this equilibrium double value. Perhaps 10% of the increase, or 200,000 new instances of tangible inherited defect, would occur in the first generation.

Since at various places this report considers a radiation dose of 10 r, it may be useful to state the tangible inherited defects from a dose of that size. A dose of 10 r would, on the above basis, give rise to some 50,000 new instances of tangible inherited defects in the first generation, and about 500,000 per generation ultimately, assuming of course an indefinite continuation of the 10 r increased rate and also assuming a stationary population.

These figures by no means measure *all* of the genetic damage that would result from a doubling dose; but they do make tangible and impressive the fact that a doubling dose of radiation would cause real personal and social distress.

(D) There is another way of looking at this problem of genetic damage, and that consists of trying to make some useful sort of really long-term, fully complete estimate. This consists of estimating the total number of mutant genes which would be induced in the whole present population of the United States and passed on to the next appearing 100,000,000 children, were this whole population to receive a certain total radiation dose to the gonads. In this instance we will use a dose of 10 r, since a dose of that magnitude appears later in this report in the recommendations. Having estimated this total number of transmitted mutants induced by a dose of 10 r, one then can only say, when he wishes to translate this over into harm or damage, that each one of these mutants must eventually be extinguished out of the population through tragedy. This statement does, of course, not hold in the detailed sense that one thinks of tracing each individual mutant gene until the line which bears and transmits it is overcome by the accumulating handicaps it imposes. The statement holds only in a statistical sense. Some lines of mutant gene will die out merely through normal chance procedures of inheritance. Others will multiply through these same chance procedures. But these normal chance effects cancel out; and the *statistical extinction* of the mutant genes is accomplished only through tragedy.

Concerning these estimates of total number of mutants, three things should be said. First, they are clearly not really satisfactory to any genetecist. Too much has to be assumed, too little is dependably known.

Second, this kind of estimate is not a meaningful one to certain geneticists. Their principal reservation is doubtless a feeling that, hard as it is to estimate numbers of mutants, it is much harder still, at the present state of knowledge, to translate this over into a recognizable statement of harm to individual persons. Also they recognize that there is a risk involved in extrapolating from mouse and Drosophila data to the human case.

Various remarks can, however, fairly be made in favor of this estimating attempt. Two largely independent methods lead to about the same results, and this increases one's confidence. Although the extreme ranges of the estimates differ widely, the mean estimate for any one geneticist is not very different from the mean for any other. Even the "guessing" which is involved hardly deserves that name, for it is based on long years of experience.

So that the final thing that should be said is that in spite of all the difficulties and complications and ranges in numerical estimates, the result is nevertheless very sobering.

Six of the geneticists of this committee considered the following problem: suppose the whole population of the United States received one dose of 10 roentgens of radiation to the gonads. What is the estimate of the total number of mutants which would be induced by this radiation dose and passed on to the next total generation of about one hundred million children? Each geneticist calculated what he considered to be the most probable estimate, and then bracketed this by his minimum and maximum estimates. Each thus said, in effect: "I feel reasonably confident that the true value is greater than my minimum estimate and less than my maximum. My best judgment, as stated in a single figure, is what I have labelled the most probable estimate."

The most probable estimates as thus calculated by the six geneticists do not differ widely. They bunch rather closely around the figure 5,000,000. Four of the six estimates are very close to that figure, and the other two differ only by a factor of 2.

These six geneticists concluded, moreover, that the uncertainty in their estimation of the most probable value was about a factor of 10. That is to say, their minimum estimates were about 1/10, and their maximum estimates about 10 times the most probable estimate.

This calculation assumes a stable value for the total population. This calculation is admittedly somewhat complicated and disappointingly vague. It is, to some geneticists, not a very meaningful way of looking at the problem. To others it adds up to something at least reasonably clear, and in any event very serious.

(XIII) FALL-OUT

There has been concern about the possible genetic harm due to the fall-out of radioactive material which results from the testing of atomic weapons. Certain aspects of this problem will be discussed in the reports of the other committees of this study (fall-out on grazing and cropland; fall-out in the sea and possible concentration in marine organisms; the distribution of fall-out material by the winds and in the upper atmosphere; possible pathological damage due to long-lived isotopes built into our bones; etc.). The present comments relate only to the question of genetic damage.

From the point of view of this Committee there are two summary remarks that should be made. First, since *any* additional radiation is genetically undesirable the fall-out dose is genetically undesirable.

Second, the fall-out dose to date (and its continuing value if it is assumed that the weapons testing program will not be substantially increased) is a small one as compared with the background radiation, or as compared with the average exposure in the United States to medical X rays.

(XIV) RECOMMENDATIONS

In light of the considerations which have been reviewed by this Committee, and which have been, at least in major outline, summarized in this report, this Committee has several recommendations.

These recommendations should all be interpreted in the light of the basic fact that *any* additional radiation is genetically undesirable. Therefore our society should hold additional radiation exposure as low as it possibly can. If certain figures (such as 10 roentgens) occur in a recommendation, it should most emphatically not be assumed that any exposure less than that figure is, so to speak, "all right": nor should it be for a moment assumed that disaster will suddenly descend if one of these figures is exceeded.

In any case in which a figure is stated, it is with the idea: stay just as far under this as you can; do not consider that this is an amount of radiation which is genetically harmless, for there is no such figure other than zero.

Opposing the fact that any further radiation is genetically bad is the practical fact that further radiation, from certain sources at least, is probably inevitable. The factors which argue for an increase in radiation are not genetic, and should obviously be appraised by a group much more representative than this Committee. Thus our recommendations will have to be evaluated by others, who must decide what decisions society should or must make. As geneticists we say: *keep the dose as low as you can.*

Thus we recommend:

(A) That, in view of the fact that total accumulated dose is the genetically important figure, steps be taken to institute a national system of radiation exposure record-keeping, under which there would be maintained for every individual a complete history of his total record of exposure to X rays, and to all other gamma radiation. This will impose minor burdens on all individuals of our society, but it will, as a compensation, be a real protection to them. We are conscious of the fact that this recommendation will not be simple to put into effect.

(B) That the medical authorities of this country initiate a vigorous movement to reduce the radiation exposure from X rays to the lowest limit consistent with medical necessity; and in particular that they take steps to assure that proper safeguards always be taken to minimize the radiation dose to the reproductive cells.

(C) That for the present it be accepted as a uniform national standard that X-ray installations (medical and nonmedical), power installations, disposal of radioactive wastes, experimental installations, testing of weapons, and all other humanly controllable sources of radiations be so restricted that members of our general population shall not receive from such sources an average of more than 10 roentgens, in addition to background, of ionizing radiation as a total accumulated dose to the reproductive cells from conception to age 30.

(D) The previous recommendation should be reconsidered periodically with the view to keeping the reproductive cell dose at the lowest practicable level. If it is feasible to reduce medical exposures, industrial exposures, or both, then the total should be reduced accordingly.

(E) That individual persons not receive more than a total accumulated dose to the reproductive cells of 50 roentgens up to age 30 years (by which age, on the average, over half of the children will have been born), and not more than 50 roentgens additional up to age 40 (by which time about nine-tenths of their children will have been born).

(F) That every effort be made to assign to tasks involving higher radiation exposures individuals who, for age or other reasons, are unlikely thereafter to have additional offspring. Again it is recognized that such a procedure will introduce complications and difficulties, but this committee is convinced that society should begin to modify its procedures to meet inevitable new conditions.

(XV) CONCLUDING COMMENTS

The basic fact is—and no competent persons doubt this—that rediations produce mutations and that mutations are in general harmful. It is difficult, at the present state of knowledge of genetics, to estimate just how much of what kind of harm will appear in each future generation after mutant genes are induced by radiations. Different geneticists prefer differing ways of describing this situation: But they all come out with the unanimous conclusion that the potential danger is great.

This report recommends that the general public of the United States be protected, by whatever controls may prove necessary, from receiving a total reproductive lifetime dose (conception to age 30) of more than 10 roentgens of man-made radiation to the reproductive cells. Of this *reasonable* (not *harmless*, mind you, but *reasonable*) quota of 10 roentgens over and beyond the inevitable background of radiation from natural causes, we are now using on the average some 3 or 4 roentgens for medical X rays. This is roughly the same as the unavoidable dose received from background radiation. It is really very surprising and disturbing to realize that this figure is so large, and clearly it is prudent to examine this situation carefully. It is folly to incur any X ray exposure to the gonads which can be avoided without impairing medical service or progress.

The 10 roentgen recommendation applies in an average sense to the population as a whole. We also include a recommendation concerning the upper limit of exposure that any one individual should receive. These limits would of course apply to persons whose occupations involve radiation exposure, but they are intended as broad and uniform regulations which apply to any and every individual.

The fall-out from weapons testing has, so far, led to considerably less irradiation of the population than have the medical uses—and has therefore been less detrimental. So long as the present level is not increased this will continue to be true; but there remains a proper concern to see to it that the fall-out does not increase to more serious levels.

One important lesson which results from this study is the following: The present state of advance in atomic and nuclear physics on the one hand, and in genetics on the other hand, are seriously out of balance. We badly need to know much more about genetics—about all kinds and all levels of genetics, from the most fundamental research on various lowly forms of life to human radiation genetics. This requires serious contributions of time, of brains, and of money. Although brains and time are more important than money, the latter is also essential; and our society should take prompt steps to see to it that the support of research in genetics is substantially expanded and that it is stabilized.

We ought to keep all of our expenditures of radiation as low as possible. Of the upper limit of 10 roentgens suggested in Recommendation C, we are at present spending about one third for medical X rays. We are at present spending less—probably under one half a roentgen—for weapons testing. We may find it desirable or even almost obligatory that we spend a certain amount on atomic power plants. But we must watch and guard all our expenditures. From the point of view of genetics they are all bad.

SUMMARY REPORT OF THE COMMITTEE ON PATHOLOGIC EFFECTS

Appreciation of the pathologic effects of radiation on man has required of this Committee and its subcommittees, consideration of voluminous experimental work on animals, as well as such direct data on human beings as are available. When the results of controlled experimental studies are considered in the light of the human data, it is found that the sequence of pathological changes is indeed quite similar in man and in animals, although man has certain definable peculiarities of response.

The human data include:

Results of excessive exposure to X-rays and radium in the early days;

Results of more moderate exposure to different forms of radiation, as experienced by cyclotron workers;

Results of introduction of naturally occurring radioelements into the body, notably radium preparations and thorotrast;

Effects of exposure at Hiroshima and Nagasaki;

Observations on populations irradiated by fallout;

Additional observations from clinical radiotherapy, use of artificial isotopes in therapy, a very limited number of accidents in atomic energy work, and certain statistical surveys of large groups.

Experimental work covers the whole field and includes studies of acute and chronic effects on many species of animals.

Certain human effects have to be assumed from consideration of experimental knowledge: for example, early effects of high doses to the central nervous system, and results of absorption of most of the artificially produced isotopes, and it is fair to say that the lethal dosage of penetrating radiation for man is less well known than for many other species.

Radiation has been added to the means of production of casualties in warfare. Not only can radiation cause death or immediate, or delayed injury by itself, but exposure to it intensifies the seriousness of burns or other injuries. The acute lethal dose for half of a given population is in the range of 400 to 600 r.

Despite the existing gaps in our knowledge, it is abundantly clear that radiation is by far the best understood environmental hazard. The increasing contamination of the atmosphere with potential carcinogens, the widespread use of many new and powerful drugs in medicine and chemical agents in industry, emphasize the need for vigilance over the entire environment. Only with regard to radiaion has there been determination to minimize the risk at any cost.

It appears, however, that a fairly clear general picture of human radiation effects can be presented. Members of this group and of its subpanels, while recommending various points of departure for greater consideration and further research, were in no case of the opinion that any sort of "crash program" would be desirable or profitable.

The various means whereby persons may be overexposed to radiation will have a great deal of influence on the over-all effects. For example, the exposures at Hiroshima and Nagasaki and a few exposures in accidents in atomic energy plants, involved radiation to the whole body in which the clinical effects reflected mainly injury to the blood-forming tissues and intestinal tract. These tissues are very sensitive to radiation but have a great power of recovery.

Where, on the other hand, exposure has been suffered at a relatively low level from time to time over a period of years, a variety of injurious effects may be encountered, such as leukemia and skin cancer. Among those who have adhered to present permissible dose levels, none of these effects have been detected.

Shortening of life span may result from exposure to radiation not only as a consequence of damage to a specific tissue, as seen in the development of skin cancer and leukemia, but also as a result of such general factors as lowered immunity, damage to connective tissue, or premature aging. Older members of the populations seem to be more sensitive to this nonspecific damage. The shortening of life correlates roughly with dose of radiation, but has not yet been demonstrated at low doses. The following table indicates life shortening in radiologists, who may well have received doses in the course of their occupation ranging from very slight to about 1000 r.

Average age at death

	Years
Physicians having no known contact with radiation	65.7
Specialists having some exposure to radiation (dermatologists, urologists, etc.)	63.3
Radiologists	60.5
U. S. population over 25 years of age	65.6

Shielding of even a portion of the body from radiation lessens the effect out of proportion to the relative amount of tissue protected. Therapeutic radiation to a single portion usually is much greater than the lethal level of total body radiation.

Radiation may have its prominent effects in particular parts of the body when it is applied locally, and this may take place in two ways. First, an external source may be so handled as to direct its radiaion to a particular part; in this way many of the early radiologists suffered acute or chronic injury to the hands, which has also occurred in more recent atomic energy accidents.

In the second instance, a radioactive substance may be taken into the body and deposited where it is a source of constant local irradiation until it is eliminated. Bone disease in radium workers and lung disease in miners of radioactive ores (both leading to cancer as a late development) are well-known examples of this mode of exposure. It is worth noting that the atomic energy industry, through diligence, has apparently avoided exposures leading to this type of injury.

It is thus characteristic of the radiations that their effects may manifest themselves not only immediately, but perhaps only after a long period of intermittent radiation, or may even be long delayed after a single exposure. One of the particular tasks of the panel has been to see all of these effects in a common perspective. They will be discussed here in terms of the effects of radiation on the important organs and tissues of the body, since it is a well known fact that some are more readily injured by radiation than others, and that injury to some has more serious consequences than to others.

Among the more serious effects of radiation are those on the blood, since the vital blood forming organs are particularly sensitive to radiation injury. The white blood cells are decreased in number soon after radiation, and in fatal cases they almost disappear before death. Other acute changes in the blood give rise to disorders in the clotting mechanism and a bleeding tendency, and the formation of antibodies against infections is impaired. These changes lead to acute illness in the second week (perhaps a little later in man), heralded by decrease in the white cells.

In the next few weeks anemias may occur due to deficiencies in red blood cell formation and survival. Those victims living through the first month usually recover, but in certain individuals, or where radiation is continued, there is a further serious breakdown of blood cell formation.

Some late effects of radiation appear as leukemias, which are found to arise a few years after radiation. This disease, relatively rare in man, may show manifold increase in persons subjected to a nearly fatal single dose (Hiroshima data) or in those whose professional work has exposed them to higher than acceptable permissible dose rates.

Effects on the intestinal tract are also critical in the early period. Vomiting and diarrhea occur within a few hours. This is a common complication of X-ray treatment to the abdomen, but is not fatal. It seems to be mediated through the vegetative nervous system and is probably not related to later damage.

Within a few days (usually four or five) after radiation, more serious effects occur. Failure of the cells lining the intestine to replace themselves results in denudation of the surface, with intractable loss of fluid and salts; complicated by ulcerations, spread of infection, and bleeding.

Late effects are seen after heavy radiation therapy, and resemble those seen in some other heavily irradiated tissues: overgrowth of connective tissue (fibrosis) and decrease in the number of functioning epithelial cells. Cancer has occurred in animals given overwhelmingly large doses of isotopes in insoluble form by mouth.

Effects of radiation on skin have been widely observed. On the first day an erythema, resembling that of sunburn, appears but is transitory. A few days later a somewhat more persistent erythema occurs which may be associated with pigmentation. Ulceration may occur in this period after high doses. Much later, atrophic changes are seen, with marked deficiency of the blood supply and intractable ulceration; such a chronically damaged skin is a fertile bed for cancer development. The Marshall Island group, while receiving total body radiation insufficient to produce serious changes, had rather marked secondary skin lesions from direct contact with fallout material. Slight local vascular changes have been observed after two years, but serious after effects are not anticipated. Falling of hair was temporary in these persons; heavy dosages are required to make it permanent. In animals, destruction of the pigment cells causes regrown hair to be white, but such loss of pigment seems not to take place in men under comparable conditions.

Bone: Early radiation effects are not of note, except that retardation of growth of epiphyses of immature bones occurs and may produce serious results in children given local radiation therapy. Late effects are seen in radium poisoning, where we see repeated destruction and repair, culminating in widespread destructive changes in which bone sarcoma is likely to appear.

Lung: Early after large doses we see congestion and increased secretion. Here, again, the late-appearing changes are of greatest importance: fibrosis, and development of cancer, which has been very common in mining areas where large concentrations of radon gas were inhaled.

Thyroid: An early and persistent effect is depression in secretory activity, which is used as the basis of the radioiodine therapy of hyperthyroidism. No serious late local effects of thyroid radiation in adults have been recorded, although some leukemias have followed heavy radioiodine treatment. A small proportion of children treated with X-ray to the upper part of the body, however, develop thyroid cancer later on, suggesting a specially high sensitivity of the child's thyroid.

Eye: The only noteworthy lesion is cataract of the lens, which is a late response. It is much more readily produced by neutrons than by X-rays, therefore, has been most prominently observed in cyclotron workers.

Gonads: A single sublethal radiation dose to a male may result in sterility after two to three weeks, followed by a slow recovery. Chronic treatment results in a gradual reduction in number, motility and viability of sperm. This is the most sensitive indicator of chronic damage so far observed, being measurable in dogs at ten times the permissible dose rate. Larger doses (about equal to the total-body lethal dose) permanently sterilize males and females. Experience with the Marshall Islanders, the exposed Japanese, and certain accident cases indicate that total body doses up to about 40–50% of the lethal have no permanent effect on human fertility.

Central Nervous System: Observations in man are quite limited. Very high doses given to animals result in loss of coordination and excitement soon after

irradiation. At later stages, various effects are seen which indicate sensitivity of particular cells and areas.

Effects on Embryos: Treatment of embryos at various stages of development may lead to highly specific malformations depending on the exact developmental stage at the time of irradiation. At critical stages, relatively low dosages (those permitting survival of the mother) may cause serious malformations. These changes must be distinguished from genetic mutations, as one is often tempted to call abnormal offspring mutations. The type of malformation discussed here would not perpetuate itself genetically, and would result from radiation during gestation.

It must also be remembered that there are various other agents causing malformations during development, of which German measles is a well-known example.

A few factors influencing sensitivity might be mentioned. Very young or very old animals have increased sensitivity to lethal effects. Growing tissues are generally more readily damaged. States like hibernation delay the appearance of radiation damage but do not prevent it. Moderate stresses seem not to effect sensitivity but severe ones such as burns or exhausintg exercise, have a deleterious influence, augmenting sensitivity.

Local radiation in sufficient amount to almost any part of the body may produce cancer, the chance of tumor development being somewhat related to dose. Since the cancer cell is an altered type of a normal tissue cell, it has often been suggested that cancer is a somatic mutation, like a genetic mutation but arising in a tissue cell which perpetuates the character by its growth.

All types of induced and spontaneous tumors appear not to arise at once, but to pass through a serious of preliminary stages; and radiation induced tumors take a particularly long time to develop. Radiation induced cancer occurs in the absence of a generally abnormal state of the tissue of origin. Mouse experiments show that shielding of a part of the body will prevent radiation leukemia and that shielding of one ovary will prevent tumor from developing in the other; and several of the tumors appearing late after irradiation seem to be produced in response to indirect mechanisms. If somatic mutation is a necessary part of the induction of cancer, it would seem to play a minor role.

We have so far considered effects of overdosage of radiation in various forms. The question must necessarily be considered, as to whether much smaller amounts of radiation harmless to individuals, might be deleterious to large populations. Because of the striking difference of germinal and somatic cells the former carrying on from generation to generation injuries received, the Genetics Committee has recommended for large populations permissible dose levels of radiation lower than those which are safe for any one generation. As the permissible dose level which they have hypothesized as desirable for large populations were to be applied there would be no demonstrable somatic effect, although a theoretical minor shortening of life span could not be ruled out.

As regards internal contamination, independent data on Rongelap inhabitants and Japanese fishermen indicate that a considerable proportion of the lethal dose of external radiation was received by individuals who barely exceeded, and only for a short period, the permissible internal burden.

The only situation worth considering in relation to large-scale pathologic effects would then be widespread contamination with Strontium–90, which is a long-lived (half life 10,000 days) readily absorbed, bone-seeking isotope which tends to fall out generally over the earth rather than in accordance with the usual close or intermediate fallout pattern. It has already been found that some young individuals have retained 0.001 microcuries or one-thousandth of the permissible dose. This amount if maintained through life would yield 0.2 rep (equivalent r) to the skelton.

In developing an unequivocally safe amount, we can recall that a certain degree of radiation exposure has always been with us, even excluding X-rays, in the form of gamma radiation from minerals, cosmic rays, and radioelements normally in the body. These levels vary greatly from one location or altitude to another and are not considered to produce harmful effects.

There seems no reason to hesitate to allow a universal human strontium (very similar chemically to calcium) burden of 1/10 of the permissible, yielding 20 rep in a lifetime, since this dose falls close to the range of values for natural radiation background. Visible changes in the skelton have been reported only after hundreds of rep were accumulated and tumors only after 1500 or more.

In relation to world-wide contamination, food chains are important. Fallout contaminates plants through ground and leaf deposition; animals eat these plants. Because in fact milk and cheese are human sources of radiostrontium, being high in calcium. Throughout this chain, strontium is discriminated against relative to calcium, which reduces the hazard somewhat. It must be remembered that in regions where soil and water are low in calcium, calcium and strontium will be more readily taken up.

As to therapy of radiation injury: while treatment is difficult, some success has been achieved with antibiotics and properly timed blood transfusions. Shielding of a portion of the body appears to give a degree of protection disproportionately large for the mass shielded. Experiments set up to explain this fact may help in developing a rational treatment. Also, various forms of treatment given immediately before radiation have been devised, but do not appear in any sense practical. Studies of this sort may, however, provide a basis for future discoveries.

Because of the nature of this report, specific recommendations regarding needed research are omitted here, but will be published later when the subcommittee reports and other appendices are published in full.

SUMMARY REPORT OF THE COMMITTEE ON METEOROLOGICAL ASPECTS OF THE EFFECTS OF ATOMIC RADIATION

CHAPTER I. DEBRIS FROM NUCLEAR TESTS

A. Introduction

Nuclear weapons produce atomic clouds which rise to heights dependent principally upon the energy released and also on the type of burst (air, surface, underground, etc.). Weapons in the kiloton range leave most of their radioactive debris in the troposphere, while megaton weapons are powerful enough to inject significant quantities of radio-active material into the stratosphere. Once the debris is injected into the atmosphere, it is rapidly spread over the earth by atmospheric processes, and eventually deposited on the surface of the earth, in a complex manner. Among the many problems are included: the way in which debris is mixed and transported by the atmosphere, both vertically and horizontally, the mechanism of removal from the troposphere and deposition on the ground, and the rate of penetration from the stratosphere through the tropopause and into the troposphere for eventual removal.

1. *Categories of fallout.*—The problem of the removal of radioactive debris from the atmosphere and its deposition in the biosphere may be divided into three phases: (1) Early or "close-in" fallout, that which occurs within the first ten to twenty hours following a nuclear explosion; (2) Intermediate fallout, that which occurs during the first weeks following the burst; and, (3) Delayed fallout, the slow removal of small particles which may continue for months and even years, particularly after a high-yield thermonculear explosion.

The principal mechanisms by which the removal occurs are gravitational settling, scavenging of radioactive particles by falling precipitation, and deposition by diffusion resulting from the everpresent turbulent eddies of the atmosphere. Although all principal mechanisms of removal play a role in each phase of the fallout, the primary emphasis shifts from gravitational influences in the early fallout to precipitation scavenging in the intermediate phase to an as yet poorly understood combination of diffusion and scavenging in the delayed fallout.

2. *Measurements.*—The most direct measurement of radioactive deposition is that made from the soil since it represents the main natural surface onto which the particles fall. Difficulties arise from the fact that rain may remove some of the activity by runoff or soaking deeper into the ground. As a measure of the true radioactivity on the ground in determining plant or animal intake of strontium 90, for example, soil sampling is obviously the most acceptable solution. But, for an accounting of the amount which has been deposited, the soil analysis may be unsatisfactory if the sampling is performed, at say, yearly or multiyearly frequency. Soil sampling on a frequent basis may be impractical.

Measurement of radioactivity by use of hand monitoring equipment is standard practice in areas where the radioactive deposition is significantly above normal background. This kind of observation is almost entirely useless outside of the areas of close-in fallout.

For daily, weekly or monthly fallout collections, the New York Operations Office of the Atomic Energy Commission recommends the use of a one-square-foot sheet of gummed film mounted horizontally on a stand three feet above the ground. An extensive, world-wide network of daily gummed film collection at about 250 locations has been operated by the Atomic Energy Commission for several years.

Finally, since there is evidence that much of the radioactivity deposited outside of the close-in area is brought down in precipitation, the collection of whole water samples is a method of obtaining the radioactivity of particles.

Air concentration.—Measurement of air concentration near the earth's surface has been achieved by a variety of sampling procedures. Filtration equipment of many types has been successfully employed, but the efficiency of the filter material for various particle sizes, particularly in the sub-micron range, must be determined before quantitative interpretation of the data can be made.

The fact that the upper atmosphere contains significant atomic debris has been known for several years. Sampling of the upper air by aircraft has been achieved by using the motion of the aircraft to pass air through a filter paper. The British report the presence of fission products at the peak altitude of their aircraft, 48,000 feet. The Japanese have measured the radioactivity by carrying aloft Geiger counters on balloons. By subtracting the cosmic ray counts from the total, the remainder is ascribed to fission products. American scientists do not view this procedure with favor for the low levels of radioactivity found over most of the world.

Instrumentation for the measurement of radioactivity by its effects on the electrical properties of the atmosphere also are of use only in those regions where the fission product concentrations are comparatively high.

B. Close-in fallout

1. *Description.*—Close-in fallout is the radioactive material from an atomic explosion which is deposited on the ground within a few hundred miles of ground zero, and which is down in some ten to twenty hours.

There is a fundamental difference between the fallout from an atomic device detonated at the ground and the fallout from one detonated so high that the fireball does not touch the ground. In the case of the surface burst, large quantities of surface material are broken up, melted, and even vaporized, and some of this material comes in intimate contact with the radioactive fission products. Then, after the atomic cloud has stopped rising and the violent updrafts associated with the explosion have subsided, the larger and heavier particles start falling back to the ground. The result is an area around ground zero and extending downwind which is covered in a more or less systematic way with radioactive particles.

In the case of an air burst in which the white-hot fireball never reaches the surface, the radioactive fission products never come into close contact with the surface material; they remain as an exceedingly fine aerosol. At first sight this might be thought to be an oversimplification, since there have been many cases in which the fireball never touched the ground, but the surface material was observed to have been sucked up into the rising atomic cloud. Actually, however, in such cases a survey of the area has shown that there has been a negligible amount of radioactive fallout on the ground. Though tons of sand and dust may have been raised by the explosion, they apparently did not become contaminated by fission products.

Experience has shown that an atomic device exploded on the surface distributes about 70–80 percent of its fission products on the ground within a few hundred miles of the burst point. A somewhat larger percentage will take part in the close-in fallout from an underground burst, and a smaller percentage will be scavenged from a near-surface burst or tower shot.

In order to make a quantitative study of the manner in which close-in fallout occurs, one must have a knowledge of the following parameters: wind structure, yield and height of burst, and kind of surface.

As each particle falls, it is carried horizontally by the wind at each level. The time during which it is falling through a given layer is inversely proportional to its rate of fall. Thus its horizontal travel during its entire fall from an initial height can be expressed as a summation of its horizontal travel in each layer. The rates of fall of atomic particles vary with particle size, shape, density, as well as the altitude.

Although no experimental information is available on the effects of precipitation during this initial stage of the atomic cloud, it is evident that significant deposition can occur from this cause. However, the effect would be most marked

from smaller yield bombs, since the bulk of the debris from larger bombs rises well beyond the rain-bearing strata.

2. *Height and size of the atomic cloud at the time of stabilization.*—It is evident that the physical size of the atomic cloud will have an effect on the distribution of the close-in fallout. The height to which the debris is carried will determine how far downwind a given particle size will drift, and the horizontal extent will serve to spread the fallout over a larger area.

In the first few seconds following an atomic detonation, the fireball grows rapidly, until the pressure inside the fireball is roughly that of the ambient air. At this point its temperature is still many thousands of degrees higher than that of the atmosphere around it, so it is much less dense, and the buoyancy of the atmosphere forces it to rise. However, it does not necessarily rise like a hot "bubble" or balloon, but in most cases, it develops a strong toroidal internal circulation and rises in the form of a smoke ring.

As the smoke ring rises, its internal circulation draws air in at the bottom and incorporates this new air into the cloud. The result is a very large growth in the size of the cloud as it rises, due mostly to the entrainment of the air from each level through which it passes.

It is clear that the cloud will gradually cool during its rise, due to radiation, the entrainment of the outside air and adiabatic expansion. When the mean temperature inside the cloud is the same as that of the ambient air at the same level, there will be no further buoyancy and the cloud as a whole will cease rising. However, at this point the kinetic energy of the toroidal circulation may still be considerable. For devices with yields of a few kilotons, the smoke ring circulation breaks up at about the same time that it reaches its point of stabilization, but for devices in the megaton range this toroidal circulation continues to pump air in at the bottom for ten to twenty minutes.

The net result of this pumping action after stabilization is a significant increase in the horizontal size of the atomic cloud, since the air which is drawn in at the bottom is forced out radially. Observations of this effect in the case of megaton devices are hindered by the fact that the structure of the cloud becomes confused.

The atmospheric stability will vary with season and latitude, and this accounts, in part, for the difference between the altitude of a cloud detonated in a tropical atmosphere and one of the same yield in a middle-latitude winter atmosphere. The most noticeable difference between these two regimes is the height of the tropopause.

3. *Distribution of radioactivity within the cloud.*—Since it is difficult to obtain enough samples of the radioactive debris while it is still within the cloud to determine its initial distribution, the most reliable estimates of this distribution have been based on the observed fallout and a reconstruction of what this initial distribution must have been.

It is clear from the observations of the rising cloud that almost all of the lighter debris is carried aloft in the smoke ring cloud. Apparently a certain fraction of particles are large enough to be thrown out of this ring, and these are left behind in the stem. However, in the stem there are violent updrafts for the first few minutes, so all but the very large particles will continue to be carried aloft.

For a surface or near-surface burst, the type of terrain must have a significant influence on the particle size and activity distribution within the cloud.

4. *Prediction of close-in fallout.*—At the outset it would be well to state what use can be made of a prediction of the fallout area from an atomic burst. At the risk of oversimplifying the case, here are some of the pertinent factors:

> Wind observations, now almost invariably made with sounding balloons, give winds which are not entirely representative of the winds which will affect the falling atomic debris. This is because winds change with time and place and because wind observations, as all meterologists recognize, are subject to a certain amount of error. Forecast winds, by the same token, are usually even further in error. A number of studies have been made of this subject. For example, a recent study by the Air Weather Service indicates that mean vector errors in 24-hr forecasts range from about 60 percent of the observed wind at middle altitudes to over 70 percent of the observed wind at 100 mb (about 53,000 ft.). These mean vector errors correspond to wind errors of 18 to 29 knots. It is perhaps significant that these forecast errors at the higher levels (40,000–55,000 ft.) are about the same as the root-mean-square deviation of the wind from the mean wind, and at lower levels (about 20,000 ft.) the 24-hr forecast error is about

half that of the normal climatological deviation. If one had to rely on forecasts 24-hrs old, he would be just about as well off if he used climatological data or persistence in computing the fallout.

The mushroom cloud from a multi-megaton device may rise entirely above the normal coverage of our radiosonde and RAWIN network, since it is generally considered impractical to plot and analyze current weather data at levels above 100 mb., or about 53,000 ft. Thus, unless special efforts are made there will simply be no wind data at all for the winds which will affect the debris during the first part of their fall. The effects of vertical motions in the atmosphere, possibly including currents arising from bomb-produced fires, may also be enough to alter the fallout pattern.

It should be fairly evident from the discussion in the preceding section that there are still a number of questions concerning close-in fallout about which we are still somewhat uncertain. Any fallout computation, even given perfect information on the wind field, will have a degree of uncertainty as a result of the assumptions on which it is based.

With these factors in mind, it appears unlikely that a weather forecaster, even given the computing aids which he would need to compute a fallout pattern, could on short notice and in a time of emergency give a detailed and reliable forecast of the close-in fallout. He could with a fair degree of assurance delineate the general sectors in which the fallout would be mostly likely to occur, but he could not tell where a given dose rate contour would lie. If one is dealing with a military situation in which an enemy is dropping atomic bombs, then the forecaster's problem is further complicated by the fact that he would presumably not have accurate knowledge of the height of burst and fission yield of the weapon.

It must be emphasized, however, that the above statements do not necessarily apply to the prediction of the fallout from a test device, where many of the uncertainties mentioned can be removed. It is possible, by the use of a special upper air-sounding network, to obtain wind information over a limited area which is considerably more reliable and current than that obtained from the routine upper air net, and which extend to a greater altitude. Moreover, there is usually no doubt about the yield and burst height of the device during a test. Thus, it is much more likely that an accurate forecast of the fallout pattern can be made under the favorable conditions which exist during a test. Even here, there remains a degree of uncertainty, as witnessed by the fallout which occurred on some inhabited atolls during the 1954 tests in the Pacific—though this might have been forecast if there had been the refined fallout computing aids which exist today.

Finally, if one does not have to make use of forecast winds at all, but can introduce all the detail of a careful synoptic analysis "after-the-fact", including the time variation of the wind at each level, and compute the fallout on a high-speed computer, it is possible to reproduce the fallout patterns which have occurred from the U. S. surface bursts with considerable accuracy. The radiological monitoring data show a certain amount of spread in the observations because of the detailed effects of terrain and atmospheric turbulence. When the reconstructed pattern or computed fallout patterns are compared with observed values, the minor differences are usually accounted for by small-scale features in the wind structure. Where the winds apparently behave as expected, predictions verify within a factor of two over most of the area. Where they do not, the peak dose rate is often correctly predicted at various distances from ground zero although displaced relative to the observed peaks.

C. Intermediate fallout

Although gravitational settling continues to play an important role for many days, and the downward diffusion of debris from the atomic cloud as it is moved about by the upper winds also becomes important, the primary removal of debris after the first day or two following a burst occurs in areas of precipitation. As the cloud of debris continues to be diluted by the atmosphere, concentrations decrease and it becomes necessary to collect the fallout and wait until the natural radioactivity has decayed before measurements can be made.

From Nevada test series, it has been found that less than 5% of the total beta radioactivity produced is collected by the gummed film network in the United States. Stewart, Crooks, and Fisher have estimated from observations in the British Isles that about half the radioactive dust in the troposphere from Nevada tests is deposited in approximately 22 days and that 80% of the deposition by rain occurs during the first transit of the cloud over England.

The importance of precipitation in bringing debris to the ground after the first day or so following an atomic explosion is strikingly shown in the average daily activity found on gummed films exposed in the United States during the Teapot Nevada test series in the Spring of 1955. In light rain, on the average, over twice as much activity is collected by the gummed film as compared to dry days and this increase becomes more apparent as the rain gets heavier. Various studies have shown that anywhere from four to more than ten times as much debris is deposited during periods of rain as compared with dry days.

On a few occasions, rain has coincided with the passage of a fresh cloud of debris from a Nevada test, resulting in local increases of background radiation to about 1 mr./hr. beyond a few hundred miles from the test site.

In the absence of precipitation, the effects of turbulence as well as gravitational settling are important.

Removal of debris by impaction on natural surfaces, buildings, etc., resulting from the movement of air around these surfaces must be appreciable. Various studies have shown radioactive particles are found on leaves, branches, etc. An experiment conducted at the Naval Research Laboratory with an 80-mesh stainless steel wire screen and with ordinary cheesecloth faced into the wind showed that in the absence of rain as much as 10 to 100 times the activity collected on the horizontal gummed film can be collected on the screen or cloth. In a two-month period during the Teapot series, a total of 50% more activity was collected on the cheesecloth than on a horizontal gummed film of similar size. Studies of the vertical distribution of chloride particles also indicate a depletion near the ground over land areas, presumably a result of impaction on natural surfaces.

D. Delayed fallout

In contrast to the results from the Nevada tests, measurements of radioactive debris concentrations in the troposphere showed a continued increase over England during the 10-month period following the thermonuclear tests in the Pacific in 1954. Similar increases in ground-level concentrations have also been observed by the Naval Research Laboratory in the United States and elsewhere.

This delayed fallout is a consequence of the extreme heights reached by debris from thermonuclear explosions, more than 80,000 feet, which results in the storage of large amounts of small particle-size debris in the stratosphere. The existence of such a distribution has been confirmed by aircraft measurements over the British Isles in August and September 1954 and again in early 1955 which show a very large increase in air concentration above about 35,000 feet. This debris eventually moves through the tropopause into the troposphere, from where it is removed by precipitation scavenging and by deposition.

1. *Transport in the stratosphere.*—The stratospheric levels in question are mainly in a region where relatively sparse synoptic data on the structure or air currents are available. However, they are mainly in a region of hydrostatically stable air and soundings indicate, in general a relative high degree of steadiness of stratospheric currents.

The winds in the stratosphere seem to have a predominant zonal component. The material injected at a certain locality will spread to other longitudes faster than to other latitudes. Material injected at a certain time in a vertical column may move more rapidly, or even in a different direction, at one level with respect to another. This shearing motion of the large-scale air currents represents a powerful factor for the spreading of an originally localized cloud to all longitudes within a few weeks.

All stratospheric circulation cells undergo more or less marked changes during the course of the seasons. Superimposed on the seasonal trend are day-to-day wind fluctuations caused by migrating or oscillating pressure systems. The present-day knowledge of independent stratospheric pressure systems is very limited. But it can be assumed that the stratosphere reacts, at least partly, to the migrating cyclones and anticyclones of the troposphere. Over periods of several weeks the net effect of the stratospheric wind variability will be similar to a process of large-scale eddy diffusion acting mainly in the horizontal directions.

2. *Diffusion in the stratosphere.*—One may approach the question of vertical diffusion in the stratosphere in three ways: first, using first principles; second, using natural gaseous tracers and third using man-made probes.

(*a*) *First principles.*—If asked for criteria to predict vertical mixing at the ground from meteorologically-observed parameters, one would point, in all likelihood, to three items: vertical temperature gradients, wind speed and wind shear. The greater the temperature stability the less the vertical mixing. It is primarily

on this ground that the stratosphere has been viewed as a region of quiescence in comparison with a turbulent troposphere below it.

With regard to wind speed, it seems fairly clear that an absence of horizontal kinetic energy will be associated with little or no vertical motions but, it is not evident that high wind speed necessarily will produce vertical turbulence. In any event, the lower stratosphere has a variety of speeds.

In the Richardson number, which under special conditions predicts the onset of turbulence, it is the shear rather than the wind speed which is significant. There is as large an assortment of wind shears in the stratosphere as in the troposphere, barring the layer adjacent to the jet streams in the troposphere.

One must conclude that on one count—probably the most important—stratospheric vertical mixing should be much smaller than tropospheric and that on the other two scores, it need not be.

(*b*) *Gaseous tracers.*—Ozone is the first such atmosphere property which comes to mind. It has been established that the ozone concentrations below the ozone maximum (about 25 km) are often in excess of the photochemical equilibrium amounts. It appears that the day-to-day variations and much of the seasonal variation of total ozone reflects changes in the non-equilibrium ozone in the "protected" region below the maximum. It is generally accepted that exchange processes transport ozone downwards from the region of ozone maximum. Three types of exchange process have been considered. The first involves large-scale meridional circulations in the stratosphere. There are some reasons for accepting such a meridional circulation involving both hemispheres but the evidence is not very impressive. A second exchange process is turbulent mixing. This is difficult to evaluate because of the lack of information on the magnitude of the mixing coefficient. It does seem, however, that the mixing coefficient required to provide the needed flux of ozone is not unreasonable. The third exchange process may be called "Gross austausch" since it involves the vertical motions associated with travelling cyclones and anticyclones. There is good evidence for this effect in the correlations between total ozone and the pressure field. It also provides a qualitative explanation for the annual variation of total ozone.

With the possible exception of the large-scale meridional circulation, the exchange processes described above will operate to bring ozone into the troposphere where it is destroyed at lower levels by particulate matter. The study and measurement of the ozone exchange should be applicable to the exchange of nuclear weapon debris.

Water vapor probably has no marked sink (due to cloud formations or precipitation) near the tropopause. Thus, changes in the gradient of water vapor mixing ratio should be a clue to the comparative upper tropospheric-lower stratospheric mixing intensities. The use of moisture as a tracer suggests but does not clearly indicate little vertical mixing in the lower stratosphere.

(*c*) *Man-made probes.*—Both parachutes and balloons have been used regularly to measure small-scale vertical motions in the stratosphere and the results generally reveal the stratosphere to have greater vertical motions than the troposphere. Also, aircraft report turbulence in the stratosphere. This evidence for comparatively short period vertical motions is clouded by the question of the rôle of the platform. The growth of the rising balloon, for example, alters the flow around it which may be the cause for the apparent vertical motions deduced from its ascent rate. Further, as with any measure of vertical motions, the probe does not distinguish between non-dispersive vertical motions like gravity waves, and true diffusing elements.

3. *Mixing through the tropopause.*—In a practical definition the tropopause is the level of minimum temperature of a high-altitude sounding, or the layer of maximum change of vertical lapse rate of temperature when no minimum temperature is encountered. Mean height-latitude cross sections of the atmosphere show that the tropopause is quasi-horizontal only in equatorial and polar regions, at approximately 18 and 9 km, respectively. The break occurs normally between 30 and 60 deg. latitude where the mean tropopause has either a significant slope or lacks uniqueness of definition so that multiple tropopauses are assumed by some authors even for mean conditions. Individual soundings may show considerably day-to-day fluctuations of the tropopause level, in connection with the passage of cyclones and anticyclones. Therefore, the tropopause is far from being a well defined geometrical surface and can hardly be considered an internal boundary which separates two distinct kinds of air masses. Air may move vertically through the mean tropopause level, or horizontally through the tropopause breaks. However, net radiation and convection processes are assumed to exist which result in a marked tendency towards re-establishment

of the tropopause at preferred levels just above the atmospheric layer in which the content of liquid and vaporous water is significant and condensation-precipitation cycles are dominant.

Four main types of exchange of air, or air properties through the tropopause may be distinguished: (i) small-scale vertical exchange, or vertical eddy diffusion—(ii) medium-scale penetration of tropospheric air into the stratosphere above extremely intense convective cells (heavy squall lines, frequently connected with tornadoes)—(iii) large-scale entrainment of stratospheric air into tropospheric systems such as cyclones, jet streams, hurricanes—and (iv) mean transport by vertical branches of large-scale to world-wide circulation cells.

4. *Tropospheric removal.*—The very small particles which are originally in the stratosphere and reach the troposphere weeks, months and even years after the detonation of a thermonuclear weapon, must eventually be deposited in the biosphere. However, the mechanisms by which these small particles are finally removed from the troposphere are not clear and the data concerning this problem is inconclusive.

Investigations of the rate of removal of natural radioactivity from the lower troposphere, both in the United States and in Germany, indicate that about half the activity is removed in a period of about one or two weeks. However, the particles involved are extremely small (probably less than 0.01) and are concentrated near the ground, so that the results may not be applicable to the fallout problem. On the other hand, Langmuir has shown that the collection efficiency of precipitation for very small droplets (less than 1) is small, but again the results may not be applicable to the fallout problem, where electrostatic and surface tension phenomena are different. Agglomeration between natural cloud elements and radioactive particles is operative for small particles.

Conflicting evidence on the rapidity of tropospheric removal is also found in studies of the actual fallout. Stewart, Crooks and Fisher, in Britain, estimate from indirect reasoning that deposition in rain exceeds dry deposition by a factor of twenty for thermonuclear explosions, a study of gummed film results in the United States does not bear this out—average monthly deposition at 40 monitoring stations during September and October, 1954, shows no correlation with either total rainfall during the month or the number of days with rain at the station. Again, using the British data, it is seen that the specific activity of the lower atmosphere showed a more than fourfold increase during the interval from 10 weeks after the Pacific tests to 50 weeks after if the data is corrected for decay. Similar increases were found by the Naval Research Laboratory. It is hard to reconcile this increase in tropospheric concentration with the rapid cleansing of the troposphere.

E. Analysis of stratospheric storage from radiostrontium fallout data

1. ***Statement of the problem.***—The fission product of greatest interest in terms of long-term hazard from nuclear detonations appears to be Sr^{90}, and estimates of the rate of deposition of this isotope in the biosphere are needed. Unfortunately, our knowledge of the physical mechanisms involved is too meagre to deal with this problem on a theoretical basis. Although it has been established that a considerable amount of debris is injected into the stratosphere and that this debris slowly mixes downward into the troposphere and is eventually deposited on the ground, the average storage times in the stratosphere, and even in the troposphere, are uncertain. Among the many unknowns in attempting a theoretical analysis are the initial distribution in the stratosphere and the physical mechanism of stratospheric removal. Even if the latter were known, we are at present unable to make quantitative estimates of the rates or intensities of these physical processes. However, due to the biological uncertainties in estimating the hazard from Sr^{90}, a precise answer is not needed, and even a gross estimate would be useful.

2. ***Analysis by W. F. Libby.***—Dr. W. F. Libby of the Atomic Energy Commission has published an estimate of the stratospheric storage time based on the estimated stratospheric content and on the observed deposition, with little or no reference necessary to the physical mechanisms involved. Essentially, the annual deposition is divided by the amount in the stratosphere, yielding the fractional removal during the year. If the fractional removal rate is assumed constant (i. e., the stratospheric content is assumed to decrease exponentially) the mean residence time of the debris is given by the ratio of the stratospheric content to the deposition.

The basic data used by Dr. Libby are the stratospheric content immediately after the completion of the Castle (Spring 1954) tests in the Pacific and the deposition of Sr^{90} during the following year or so as measured in three ways, a

world-wide gummed film fallout network, the Sr^{90} content of Chicago rainfall and air filter measurements at Washington, D. C. From these results, Libby concludes that the mean storage time for debris in the stratosphere is approximately 10 ± 5 years.

3. *Conclusion.*—Stratospheric storage not only serves to delay the fallout of debris, but also to disperse it over the globe, minimizing the chance of locally high concentrations of debris. At present, the amount of Sr^{90} in the stratosphere from nuclear weapon tests is far too small to approach maximum permissible concentration even if it were to be all deposited now. However, if the testing programs of the several countries producing thermonuclear weapone were to intensify, stratospheric storage time may become a critical item in terms of hazard to mankind. For this reason, a continuing program to investigate this phenomenon is needed, including actual measurements of the radioactivity in the stratosphere and improved and more representative methods of observing fallout.

CHAPTER II. ATMOSPHERIC RADIOACTIVITY FROM CIVILIAN APPLICATION OF NUCLEAR ENERGY

A. Sources of contamination

The hazards of atmospheric contamination from the military uses of atomic energy have tended to overshadow other possible sources of contamination, principally because, to date, relatively insignificant contamination has occurred from non-military sources. Certainly, the near future will see a tremendous increase in the utilization of nuclear energy for peaceful purposes, including the production of electric power, medical, industrial and agricultural applications, and nuclear propulsion of air, sea and land vehicles.

As far as can be seen today, the largest potential use of nuclear energy will be in the production of electric power and the discussion is based on this aspect of the problem, however, other applications could conceivably double the values used in the estimates given here. A consensus of estimates of global power requirements and of the proportion of this energy which will be supplied by nuclear sources indicates that by 1975 there will be a nuclear heat energy production of 10^8 to 10^9 kilowatts and by the year 2000 this will increase to 10^9 to 10^{10} kilowatts.

These rates of production will produce enormous amounts of fission products. However, most of these will be in solid or liquid form at present day processing temperatures and it can be expected that such material will not be intentionally released into the atmosphere. Of the remaining volatile fission products, storage and "cooling" of the fuel before processing can reduce the activity materially. The two volatile isotopes of most interest are 10-year krypton 85 and 8-day iodine 131. Only the 10-year krypton is sufficiently long lived to be relatively insensitive to the cooling time of the fuel before processing. There are two aspects to the problem of radioactive hazard from these sources, large-scale contamination on a global or hemispheric basis and local or regional contamination in the areas of processing plants.

B. Large-scale contamination

1. *Krypton 85.*—The long half-life of Kr^{85} results in the accumulation of this isotope in the atmosphere. If by the year 2000 nuclear thermal power has risen to 10^{10} kilowatts, the world inventory of radiokrypton would be of the order of 10^{10} curies. Mixed uniformly through the mass of the troposphere (4×10^{21} grams of air), the resulting sea-level concentrations would be less than 10^{-8} curies/meter^3. Since most of the activity is likely to be released in the middle latitudes of the northern hemisphere, large scale concentrations of 3 to 5 times the global average could be experienced in these latitudes.

No value for the maximum permissible concentration of Kr^{85} is presently available. If, from the chemical and radiological similarity, we assume that it is analogous to radioxenon, then the estimated worldwide concentration in the year 2000 is about two orders of magnitude less than the maximum permissible concentration. However, such comparisons are extremely questionable and it is important that maximum permissible concentration levels be established for Kr^{85}.

2. *Iodine 131.*—The problem of I^{131} in the atmosphere is largely dependent on the fuel recharging interval and the cooling time. For each combination of fuel cycle and cooling time it is possible to calculate the total amount of I^{131} in the atmosphere. This is an equilibrium value assuming no removal at the source or after release. Total amounts of I^{131} in the atmosphere based on the estimated nuclear energy production in the year 2000 are given in the following table.

Total I^{131} (curies) in the atmosphere per 10^{10} kilowatts of nuclear energy

	Decay time before release		
	none	10 days	100 days
Fuel recharging frequency:			
Once a year	6×10^{9}	3×10^{9}	10^{6}
10 times a year	6×10^{10}	3×10^{10}	10^{7}
Continuous	2×10^{11}	10^{11}	4×10^{7}

The present maximum permissible concentration of I^{131} is 3×10^{-9} curies/meter^{3}. If the I^{131} is mixed with the whole mass of the troposphere, then 10^{10} curies would produce the maximum permissible concentration. However, the assumption of world-wide tropospheric mixing is unwarranted for an isotope with a half-life of 8 days. Assuming the term large-scale contamination in the case of I^{131} can at most involve a 20° or 30° band of latitude in the northern hemisphere, and that vertical mixing may be incomplete, then even for large-scale considerations an atmospheric burden of 10^{8} or 10^{9} curies of I^{131} may approach the maximum permissible concentration, and appropriate cooling or decontamination measures must be used.

C. Local contamination

It is evident that consideration of the average contamination over major portions of the globe cannot approach the hazard to be found in local areas downwind from sources of contamination. Locally, higher concentrations that would exist 10 to 100 miles from fuel processing plants (assuming something of the order of 1% of the world's fuel to be processed at any single site) could add an additional factor of 10 to 100 in the case of Kr^{85} and several thousand in the case of I^{131}. Also, transitory excess concentrations due to unfavorable meteorological conditions could raise local concentration by an additional one to two orders of magnitude.

The above effects are cumulative so that concentrations of I^{131} about 10^{4} times the global average could occur regularly near fuel processing plants in the northern temperate latitudes, rising occasionally to 10^{5}–10^{6} times the global average during unfavorable meteorological conditions. Deposition by precipitation could increase the possibilities of harmful effects. Further detailed analysis would be required in order to indicate under what conditions the concentrations of krypton, iodine, or other isotopes would exceed permissible limits. In any case, it seems that a combination of reasonably conservative fuel cooling periods, some progress in off-gas cleaning, and a judicious choice of fuel processing locations, is indicated to minimize the adverse effects of unfavorable meteorological conditions. At the larger plants, meteorological scheduling of gas releases may be required. These principles are applied today, and will become increasingly important.

D. Accidental releases

There is the possibility, even if remote, that a large high-power reactor or fuel processing facility could be damaged or destroyed by accident and release part or all of the contained fission products to the atmosphere. The results of such an event could well be catastrophic, and extend over great distances. Estimates of areas of damage range upwards of thousands of square miles for very large reactors. By the year 2000 the release of only about 1% of the worldwide Sr^{90} inventory that could then exist, even if mixed uniformly throughout the global troposphere, could produce concentrations on the order of 5×10^{-10} curies m^{-3} or about twice the currently recommended maximum permissible concentration. This same 1%, if deposited on the surface, could seriously contaminate the entire area of the earth. It is more likely, in the event of such a catastrophe, that the activity would remain concentrated in a much smaller area near the source. Still, the operation of any significant fraction of the earth's nuclear reactors without proper safeguards would be of concern to all.

E. Conclusions

The solution to radioactive air pollution problem is the same as in other air pollution problems, prevention of the escape of pollutants to the atmosphere. Thus, primary consideration must be given to engineering features limiting the

escape of hazardous gases either during normal operations or accidents. As additional safety factors meteorological research to locate plants in areas where unexpected releases will do the least damage is desirable. Finally, it should be pointed out that the release of a hazardous substance by any country may affect other countries—particularly in the same latitude belt. International control to establish and maintain high standards of safe plant operation is essential.

CHAPTER III. USE OF RADIOACTIVITY IN ATMOSPHERIC STUDIES

A. *Natural radioactivity*

There exist two important sources of naturally occurring radioactivity in the atmosphere: (1) cosmic ray interactions in the stratosphere and (2) the rock and soil of the earth's outer crust. The study of the cosmic ray induced products entails considerable difficulties because of the low level of activity. On the other hand, the radioactive substances which originate in the earth can be detected and measured with relative ease.

Radon and thoron are released as gases in the radioactive decay of radium and thorium which are found in all rock and soil. The concentration of these gases and their distribution in the atmosphere is determined by their half-lives and meteorological conditions. Although it is considered generally that the relative amounts of the various natural activities are dependent on meteorology, very few correlations with specific meteorological parameters have been made, in spite of the fact that measurements have been carried out over a period of many years. At the present time, insufficient data are available to make reliable estimates of the global distribution of radioactivity in the air over land, although it is known that at some distance from large land masses the radioactivity concentration is exceedingly low. Measurements indicate that the amount of radon decreases rapidly with altitude to about one half the surface value at one kilometer.

Radon and thoron and their daughter products would seem to provide an easily detectable tracer for the study of the vertical "Austausch." Ground level measurements indicate that exchange phenomena within even a few feet of the surface have marked effects on the concentration of radioactivity. Such measurements might well be carried on in conjunction with micro-meteorological observations. From consideration of the lifetimes of the radioactive isotopes which are involved, it is obvious that even for relatively low wind velocities, horizontal transport of these radioactivities over distances of several hundred miles is entirely possible. The study of simultaneous variations in concentration over these distances should be valuable if the locations were carefully selected to avoid the effects of terrain. Land to sea measurements should be especially interesting.

Instances of increases in radon concentration coincident with air pollution have been reported. Since atmospheric radioactivity and pollution are strongly affected by the stability of the lower atmosphere this effect is not surprising. For the same reason it is quite possible that a relationship could be established with the tropospheric scattering of electromagnetic radiation.

Experiments have shown that the radon and thoron decay products are attached to submicron particulates. The details of the attachment process are not well understood; for example the relationship between various ionic species or the number and kind of nuclei. These radioactivities exist in the form of a readily detectable submicron aerosol which generally follows the surface wind pattern. These small particles, and incidentally other pollution, appear to be removed from the lower atmosphere in a matter of days, principally through precipitation. Further study of this removal process, carried out at different locations and for a variety of climatological conditions would perhaps shed some light on the scavenging efficiency of precipitation.

The natural radioactivity of precipitation is considerable and is easily measurable. The mechanism for the entrainment of the radioactive particles in rain droplets is not certain. From theoretical considerations, the probability for attachment of these very small particles in rain is quite low. It has been suggested that the radioactive ions could themselves act as condensation nuclei. On the other hand, there is the possibility that clouds of charged radioactive particles could act as a sort of "trigger" for electrical phenomena leading to cloud electrification and precipitation. Experimentally, the difficulties of working with large volumes of rainwater are partially offset by the large activities encountered. The actual air volumes swept out by precipitation is very great

and it would seem that there are possibilities for tracing air masses by using natural radioactivity.

Traditionally atmospheric radioactivity has been associated with atmospheric electricity and might well supplement studies in this field. The radon and thoron decay products are charged and can be collected by electrical means. They are estimated to cause about one half of the ionization in the lower atmosphere. Certain of the theories of atmospheric and cloud electrification are quite sensitive to changes in the ion concentration. Since large changes in the radioactivity concentration are the rule, further studies carried out in conjunction with atmospheric electrical measurements should be valuable.

The most extensively studied of the cosmic ray induced isotopes found in the atmosphere have been C^{14}, H^3 and Be^7. Probably both short term increases in fossil CO_2 from industrial sources and the long term global distribution could be detected using sensitive techniques. H^3 is present in the air principally in the form of tritiated water and will probably find its most useful applications to hydrology, although more extensive sampling of precipitation is no doubt desirable. Because of its relatively short half-life, Be^7 may be of very great importance in the study of the rate of mixing between the stratosphere and troposphere. Unfortunately, there is a great lack of experimental information suitable for correlation with meteorological phenomena.

B. Debris from weapons tests

The debris injected into the atmosphere from the testing of nuclear weapons can provide a useful tool for investigating atmosphere phenomena. However, two basic limitations on the usefulness of the approach must be recognized:

1. The source strength and distribution in space is largely unknown. Such important information as the distribution of particles with altitude, the exact configuration of the stabilized cloud, the relation of particle size to activity, the fractionation of elements within the cloud, etc., is not available.
2. Sampling techniques are imperfect. Air concentration measurements are difficult because of the low concentrations and small particle sizes involved. Ground collections result from either deposition of the particles themselves or by precipitation scavenging.

Using the gummed paper collection system described in Chapter I, it has been possible to obtain certain valuable meteorological information on such items as: a measure of the cross-equatorial transport and some feature of the general circulation from U. S. Pacific tests, scavenging by the upper portions of rain clouds of the particulate fission products, an estimate of rapidity of the removal of particulates from the troposphere, an estimate of the rate of transport from the stratosphere to troposphere.

Using aircraft sampling procedure, it has been possible to obtain estimates of the rate of lateral spread of an atmospheric contaminant and vertifications of meteorological trajectories.

By following the Tritium released by the CASTLE series of weapons tests it has been possible to estimate the removal time for atmospheric water molecules.

It is likely that the potential of even the existing unclassified information on radioactivity released by weapons tests has not been exhausted. This potential would be enhanced by disclosure of additional information on weapons, debris measurements, and source strengths. For example, the weapons tests offer an opportunity to determine storage and transit time parameters for surface water sheds of almost any size. By comparing the amount and level of radioactivity in rainfall and runoff as a function of time following a weapons test, it would be possible to measure those parameters which are vital to studies of ground water, river runoff, and flood forecasting.

C. Artifically introduced radioactive tracers

Artifically introduced radioactive tracers can serve meteorology in at least three fields: first, through the delineation of the airflow and rates of diffusion; second, in hydrometeorology, including studies of condensation, precipitation, evaporation and hydrology; and third, in atmospheric electricity.

As a tracer of air motions, radioactive substances are in competition with fluorescent dye particles, sulfur dioxide and other non-radioactive substances. Their advantages lie in the possibility of being able to treat large-scale atmospheric phenomena which otherwise require too large amounts of source material, in being able to utilize tracers which partake in the particular process under

investigation and, in certain cases, in our ability to detect the presence of the tracer instantaneously in the field. In any specific experiment it will be necessary to weigh economic, safety and scientific factors in the use of radioactive tracers over non-radioactive tracers.

Regions in which it would be highly desirable to further knowledge concerning air trajectories are in the neighborhood of jet streams, in cols, in hurricanes to measure both the three dimensional airflow and define the air comprising the eye, and in the Antarctic. In the field of dffusion, the use of radioactive tracer material can further knowledge of diffusion near the ground for air pollution studies, etc., and of diffusion in the stratosphere and tropospheric and stratospheric mixing.

The radioactive tracer material which appears to be most promising for the above meteorological studies is tritium. Tritiated water would be washed out, thus making for additional complications. Tritium in the form of ordinary hydrogen is acceptable although costs of analysis of the sample might be high. For the large-scale experiment to establish the tropospheric-stratospheric exchange tritiated methane has been suggested. Tritium has the advantageous properties of emitting a weak beta particle, of being available without difficulty, and of having a reasonably long half-life.

Water molecules are readily marked by tritium so that in any experiment in which the travel of water vapour is desired it becomes feasible to introduce tritiated water as a tracer. If sufficient amounts of tritium were available, a large-scale experiment to study the hydrologic cycle could be devised. Even on smaller scales, tritiated water could be used to study such features as the evaporation from a ponded lake, water sources for dew, contributions of local transportation or evaporation from local bodies of water to precipitation elements, etc.

Activation analysis techniques extend the possibilities for studying very small particles (such as sodium chloride) that play an important role in condensation and ice formation. Radiosilver can be introduced in a prẽparation of silver iodide to be able to determine the presence of silver iodide in the precipitation which was alleged to be stimulated by it. By releasing another tracer which would be scavenged with equal efficiency by precipitation it might be able to determine whether the silver iodide has played a role in the formation of the precipitation.

Finally, the ionizing properties of radioactive substances can be used to make local changes in the electrical fields of the atmosphere, to determine if such changes affect weather processes.

CHAPTER IV. THE EFFECT OF ATOMIC EXPLOSIONS ON WEATHER

A. *Introduction*

From the beginning of time, man has looked beyond the field of meteorology in the hope of finding some explanation for the vagaries of weather. Many inventions of man—gunpowder, radio, airplanes, and television—have been blamed for changes in weather and climate. It is only natural that atomic and thermonuclear explosions, being among the most dramatic achievements of mankind, would come in for their share of the blame.

There seems to have been an increase in unusual and undesirable weather in the past decade. When submitted to rigorous statistical tests, these apparent abnormalities do not exceed the limits that can be expected by chance and are consistent with accepted meteorological principles involving large-scale (hemispheric) weather patterns which could not be directly affected by the explosions. The failure to detect statistically significant changes in the weather during the first ten years of the atomic age is no proof that physically significant changes have not been produced by the explosions, but it does show that a careful physical analysis of the effects of atomic and thermonuclear explosions on the atmosphere must be made.

The energy of even a thermonuclear explosion is small when compared to most large-scale weather processes. Moreover, it is known that much of this energy is expended in ways that cannot directly affect the atmosphere. Even the fraction of the energy which is directly added to the atmosphere is added in a rather inefficient manner from the standpoint of affecting the weather. Meteorologists and others acquainted with the problem are readily willing to dismiss the possibility that the energy released by the explosions can have any important direct effect on the weather processes. However, there remains the possibility that

the explosion will serve as a trigger mechanism to divert some much larger natural store of energy from the path it would otherwise have followed.

Three general means by which this might be accomplished have been considered:

1. The debris thrown into the air by the explosion may have some catalytic effect on the behavior of clouds and thereby change the regime of cloudiness or precipitation over wide areas.
2. The radioactive nature of the debris will change the electrical conductivity of the air, and this may have some effect on more directly observable meteorological phenomena.
3. The debris thrown into the stratosphere by the explosion may interfere with the passage of solar radiation and thereby serve to decrease the temperature of the earth.

Our present knowledge of atmospheric physics makes difficult a final authoritative evaluation of any of these possibilities.

The results of studies and experiments conducted by various organizations show the following:

1. The debris which has been thrown up into the atmosphere by past detonations was found to be ineffective as a cloud-seeding agent. Since the techniques for testing nucleating efficiency are not entirely satisfactory, the condensation and freezing nuclei produced by nuclear explosions and their effect on the formation of clouds and the precipitation process must be continually investigated.

2. The amount of ionization produced by the radioactive material is insignificant in affecting general atmospheric conditions. Various theories on the possible connection between the electrical properties of the atmosphere and the precipitation process are still in the developmental stage.

3. Dust thrown into the air by past volcano eruptions decreased the direct solar radiation received at the ground by as much as 10–20%. The contamination of the atmosphere by past nuclear tests has not produced any measurable decrease in the amount of direct sunlight received at the earth's surface. There is a possibility that a series of explosions designed for the maximum efficiency in throwing debris into the upper atmosphere might significantly affect the radiation received at the ground.

4. Much of the increase in severe storms reported in recent years can be traced directly to the improved methods of reporting severe storms that normally occur.

No statistically significant changes in the weather during the first ten years of the atomic age have been found, yet careful physical analysis of the effects of nuclear explosions on the atmosphere must be made if we are to obtain a definite evalution of this problem. Although it is not possible to prove that nuclear explosions have or have not influenced the weather, it is believed that such an effect is unlikely.

SUMMARY REPORT OF THE COMMITTEE ON EFFECTS OF ATOMIC RADIATION ON OCEANOGRAPHY AND FISHERIES

1. To Whom Is This Report Addressed?

In writing this report we have had four groups in mind—research administrators, statesmen, scientists and the public. For those who have responsibility for the support of research, we have attempted to outline the scientific questions that need to be answered as a basis for intelligent policy, the means by which they can be attacked by classical research methods at the outset, and the broader problems of the oceans that can be hopefully attacked by the use of radioactive tracers. For the statesmen who have responsibility for national and international policy, we have attempted to formulate recommendations, based on our present small body of knowledge and our awareness of our larger area of ignorance, concerning the national and international actions and agreements that are necessary for the happy exploitation of the oceans in the new atomic age. For the scientists, we have attempted to summarize what is known about the actual and potential effects of radioactive materials in the oceanic realm and the interest of marine

scientists in these substances. For the public, to which we all belong when we are outside our own specialties, we have summarized the levels of calculated risk that must be balanced against the wonderful promise of atomic energy for the welfare of mankind.

2. How Does the Atomic Energy Program Affect the Oceans?

We have considered three aspects of the atomic energy program that directly involve the oceans and, therefore, the marine sciences: weapons tests over or in the sea, disposal of radioactive wastes from nuclear power plants, and the use of radioactive substances in increasing our understanding of the oceans and of the creatures that live in the sea. These different aspects cannot easily be separated. Weapons tests and the disposal of radioactive wastes present great opportunities for studying the oceans. On the other hand, increased knowledge of the oceans is essential to avoid or minimize the destruction of marine resources in the development of atomic energy.

The continuing development of atomic energy will produce progressively greater amounts of radioisotopes, and with them greater amounts of radioactive waste material. Since the oceans cover 71% of the earth, and ultimately receive the drainage from the land, they are the principal reservoir where radioisotopes will finally accumulate. Relatively small quantities are now being added to the surface waters of the ocean as fallout from weapons testing programs, and in a few places as waste materials.

When nuclear reactors for the production of power are put into large-scale operation, as they certainly will be in the foreseeable future, the oceans will be seriously considered for the disposal of large quantities of wastes. Even if direct and intentional disposal at sea is not practiced, reactors may be built along seacoasts or on rivers near large population centers and accidental pollution may occur.

The problem of disposal of radioactive wastes is similar in character to, though potentially far greater in scope than other problems of pollution. An object lesson can be drawn from our experience with the disposal of human and industrial wastes in inland water bodies and coastal waters and with the smog problem that afflicts many of our large cities. During the early stages of the growth of industries and populations in cities, wastes were added to nearby lakes or bays, and to the air, in what seemed at the time to be innocuous quantities. As a matter of fact, the quantities were small enough to be purified by natural processes. In the course of time, however, the quantities increased insidiously so that today many natural waters cannot purify themselves and without expensive treatment are dangerous to humans.

In almost every case the problem was ignored until it had become formidable in magnitude. Short-range solutions were employed, based on inadequate knowledge, special interest, and what we now know was an unfounded confidence in the capacity of the atmosphere and the waters to absorb noxious substances. As a result, unnecessary damage was done to human beings and their environment. Much of this could have been avoided if an adequate program of scientific investigation had been started sufficiently far in advance and if scientifically based policies had been followed.

It is imperative that the nature of the wastes associated with the development of atomic energy be evaluated in advance. We know that purification of waters receiving radioisotope waste will proceed only by dilution, by precipitation and settling on the bottoms, and by the decay of radioactivity. Nothing could be done to reverse an undesirable accumulation that might result from ill-considered disposal of this type of waste.

There is no question of trying to keep all of this material out of the sea. It is certain that some of it can be safely added. Tolerability of materials must be determined, and the locations where they should be put must be wisely selected in terms of the quantity and character of the radioactivity. It is not possible today to see clearly the problems of the future; we can only define the studies that must be made to provide a scientific basis for wise evaluation, and urge that these studies be begun without delay. The costs of such studies may seem large, but they are actually negligible in terms of the potential benefits. They are also very small when compared to the total present expenditures for the development of atomic energy. We cannot wait to begin these studies until radioisotope pollution becomes serious, for it is irreversible.

3. Is There Naturally Occurring Radioactivity in the Sea?

Yes, but one of the remarkable characteristics of the ocean is the extremely low level of the natural radioactivity. Marine animals and plants living more

than a few hundred feet beneath the surface are bombarded by much less natural radiation (radioactivity plus cosmic rays) than is received by terrestrial plants and animals.

For example, although radio potassium accounts for about 90 percent of the activity in the sea, it is present in most igneous rocks at about 100 times the concentration found in the ocean. Uranium, radium, and thorium are 3,000 to a million times more concentrated in rocks than in the sea. This raises an interesting scientific question concerning the character of genetic change and evolution in many marine creatures. It emphasizes the need for basic biological studies on marine organisms. Because of their experimental difficulty, such studies have been comparatively neglected during the past few decades.

4. Have Weapons Tests Added Measurable Amounts of Radioactivity to the Sea?

Yes, though in terms of the total radioactivity of the sea the amount is negligible. Radioactivity in the waters of the test area is of course very greatly increased at the time of tests, and even after diffusion over thousands of miles concentrations remain that are readily detectable. Two days after the 1954 tests in the Pacific the radioactivity of the surface waters near Bikini was observed to be a million times greater than the naturally occurring radioactivity. This material was transported and diluted by ocean currents, and four months later concentrations three times the natural radiation were found 1,500 miles from the test area; thirteen months later the contaminated water mass had spread over a million square miles. Artificial activity had been reduced to about one-fifth the natural activity, but could be detected 3,500 miles from the source.

5. In What Other Ways Will Radioactive Materials be Added to the Oceans?

In England radioactive wastes are being piped into the Irish Sea from an atomic installation. In the United States, wastes from laboratories and hospitals are being carried to sea in containers and dumped. At Oak Ridge, some of the fission products are discharged into the Tennessee River system. At Hanford, water from the Columbia River is used for cooling and returned to the river with some induced short-lived radioactivity. Waste products from the uranium fuel processing plants are now being confined, some in containers, others in pits in the ground. When the power reactors and fuel processing plants reach their expected development many rivers will have to be used. It will not everywhere be practical to confine the wastes locally. Transporting them to sea in barges or by other means may then be necessary in many cases. Although we may be sure the atomic installations will be carefully engineered and maintained, accidental discharge of waste may occasionally occur. On those occasions intense radioactivity may reach the sea.

6. Has the Atomic Energy Program as Yet Resulted in Serious Damage to Marine Life?

Probably no. We know that radioactive radiation is damaging to living things and that marine organisms tend to concentrate many fission product elements. But there is no evidence that any lasting damage has been done to the animal or plant populations of the sea or large inland water bodies by the release of radioactive substances.

Certainly in the weapons test area terrestrial forms were killed or injured by the tests. The evidence concerning marine life is not conclusive, but biologists feel certain that deleterious effects occurred in the near vicinity. There is, however, no evidence that populations have been affected after the dilution and transport mentioned above. This is a subject on which intensive studies are essential before a definite answer can be given. We know that "high" levels are lethal, and that "low" levels may have no direct effect, but we cannot give quantitative values for "high" and "low" except in a few cases. Low levels, which produce no measurable effect in the organism itself, may produce genetic effects and thus influence the marine populations in the future, but there is no conclusive evidence that this will be undesirable.

7. Do Living Things Take Up Radioactive Materials into Their Bodies?

Yes. Radioactive materials added to the sea can remain in solution, precipitate and settle on the bottom, or be taken up by the plants and animals that live in the water. The plants of the sea are mainly microscopic in size, but they can concentrate many thousand-fold those elements that are necessary to them. Radioactive substances are also absorbed on the body surfaces of living things. Small plants and animals serve as food for the larger forms and the radioactive materials are passed on from one to another. The amount of each element accumu-

lated in each form depends upon the rate at which it is taken up, either directly or as food, and the rate it is excreted. Some of the radioactive materials remain in the body for relatively long periods of time and may accumulate to a considerable degree. Others may be lost rapidly and very little will accumulate.

This statement is a great over-simplification. Different plants and animals require and accumulate different elements. Shell fish, for example, concentrate calcium and strontium in their calcareous shells; fish concentrate zinc. It will be necessary to know among other things both the composition of the waste, and the populations in the area, before any particular disposal operation can be evaluated.

8. Are All the Radioactive Elements Equally Harmful?

No. Those elements that living organisms naturally accumulate and that have long radioactive half-lives are more harmful than others. Radioactive strontium, and to a lesser extent, cesium and its daughter barium, cerium, praesodymium and promethium represent particular hazards to human beings from ocean disposal.

9. How Much Radioactive Waste Will be Produced by Nuclear Power Reactors in the Future?

The answer to this depends upon how optimistic one is concerning the development of nuclear power. One estimate assumes that within about 50 years nuclear fission will be producing about half as much power annually as the peoples of the world are using today from all sources.

Accumulations year after year will eventually result in a constant quantity of radioactivity, such that the rate of radioactive decay will balance the rate of production of fission products to give what has been called the steady state. This should be approached within a few decades after full production is reached. The waste radioisotopes at this point would equal between one and two times the total natural radioactivity in the world oceans. This is roughly a thousand times the amount produced so far in weapons tests.

10. What Means Are Being Considered for Disposing of Radioactive Wastes?

The methods being considered fall into two categories, isolation and dispersal. It is probable that a judicious combination of the two methods for different types of wastes or for different countries will be essential. Chemical treatment of the wastes to isolate usable fractions, or those, like strontium and caesium, that decay most slowly, offers promise in simplifying the problem. For isolation, permanent storage in tanks or introduction into geological structures such as salt domes are being studied by other committees. The only place on earth where dispersal can be considered practical is in the ocean. Because it is large and fluid, the ocean could provide immense dilution. Because of its depth, and the stratification of water-masses with differing densities, various degrees of isolation may be possible. It is a prime purpose of this report to emphasize the need for investigation as to whether this possible isolation is adequate.

11. Will it be Safe to Introduce Very Large Quantities of Radioactive Wastes from Atomic Power Indiscriminately into the Sea?

The answer is certainly no, but the strongest negative must be given for coastal waters and for the upper water layers everywhere that are the home of commercially important fishes. These surface waters interconnect and are in continuous motion. Anything added in one spot will, in the course of a few decades at most, be carried to all parts of the world. There is no place in the sea where very large amounts of radioactive materials can be introduced into the surface waters without the probability of their eventually appearing in another region where human activities might be endangered.

It should not be forgotten that the coastal waters enter the harbors and estuaries and would carry any waste materials there with them; and that many of the major fishery resources of the world are concentrated over banks and near coasts, and would become contaminated.

We must also remember that all plants and animals in the sea, from the smallest bacteria to the largest whale, play a part in concentrating, transporting, and dispersing radioactive and other dissolved and suspended materials.

12. Does This Mean that Large Quantities of Radioactive Wastes Should Never be Dumped in the Sea?

No, not necessarily, but it does mean that the length of life of the radioactive material, its role in biological processes, and the mixing rate of the ocean should be carefully studied before large quantities of wastes are introduced into the

sea. Unfortunately, although we know the decay time of most radioactive substances, we know very little about the exchange processes in organisms and in the water. We do know that even the bottom waters of the deep ocean basins slowly exchange with those of the surface, but the rate of this exchange is uncertain.

13. From What Is Known, Where Would be the Safest Place to Dump Radioactive Wastes in the Sea?

At the present time it is only possible to give rough engineering estimates based on order-of-magnitude calculations.

Remembering the importance both of isolation (to allow time for radioactive decay) and dispersal (to reduce the amount of radioactivity per unit volume) the problem is to find places in the ocean where the rate of transfer of radioactive materials to the surface waters would be slow, or where great dilution would occur before radioactive materials came in contact with marine food products or human beings, and preferably where both conditions would prevail.

There are some places where a contaminant could be isolated for long periods. For example, it is estimated that in the deepest parts of the Black Sea the "flushing time" is about 2500 years. This is the time required for most of the deep water to move near to the surface and be replaced with new water mixing downward. In this respect the Black Sea is unique. Elsewhere the "age" of the deep water indicates that exchange with the near surface waters goes on less slowly. Thus in the deeps of the Atlantic and Caribbean the time required for replacement of the water with new water from near the surface is probably only a few hundred years. Some oceanographers believe that the Atlantic deep water sank from the surface in high northern latitudes about 150 years ago.

We are fairly certain that substantial amounts of long-lived radioactive materials, dumped on the bottom in the deep sea, would remain isolated for more than 100 years and that during this period they would become diluted by mixing through an enormous volume of deep water. We do not understand the nature of the physical and biological exchange processes between the deep and surface waters well enough to be able to say whether in the steady state, after decades of nuclear power production, deep sea disposal would give adequate protection of the commercial fisheries from long-lived fission products such as strontium. Large quantities of short-lived fission products could certainly be disposed of safely in this way.

14. Can Radioactive Materials be Used to Learn About the Oceans and to Increase the Harvest from the Sea?

Yes. For example, an understanding of the flow of material through food chains is essential to the effective use and conservation of the food resources of the sea. The natural elements used by the marine plants and their transfer to the commercially valuable fish and shellfish can be studied on a large scale, using radioactive isotopes. As these readily detectable substances are traced through the various steps of the food chain—plants, animal plankton, small fish, large fish—the efficiencies and inter-relationship of the various levels should become much better known. This knowledge is of fundamental importance for the evaluation of the potential of the living resources of the sea as a source of food and other marine products, and as a basis for their full utilization and conservation.

Radioactive materials, both natural and man-made, can also be used in the study of oceanic mixing processes and circulation. These processes serve to supply marine plants with the fertilizers they need from deeper waters, as well as to dilute and disperse radioactive wastes dumped in the sea. At present we cannot measure, but can only estimate the mixing rates. The ability to trace radioactive materials, even though present in great dilution, will permit us to obtain quantitative information. Improved knowledge of the mixing processes and of currents will help man to locate and evaluate unexploited resources of fish and other food organisms.

For example, thirteen months after radioactive materials were introduced into the seat fallout from weapons tests in the Marshall Islands, a research vessel traced their distribution in the Western Pacific. The extent to which radioactivity was taken up by plankton and fish was measured, as well as the extent to which activity was mixed downward and transported westward in the western limb of the great North Pacific eddy. These measurements showed the average speed at which materials were carried away from the test area, giving convincing proof of the transport and mixing of material over a vast region.

Large amounts of radioactive tracers ranging in magnitude from curies to megacuries can be used at sea in studying oceanographic problems, including the problems of fisheries, and thus laying the ground work for increasing our harvest from the ocean. Smaller amounts are needed in the laboratory. We are here concerned not with the general problems of physiology and biochemistry but with specific ecological studies, including investigations of the efficiency of transfer of energy along the food chain, rates of filtration, concentration of elements and compounds in various tissues, the rates of accumulation and excretion of elements and compounds, the passage of substances across biological membranes, the concentration and role of biotic and antibiotic substances in the sea, the dynamics of marine populations, including the mass of living material in a given volume of water, the flux of organic substances from one organism to the other and between the organism and the sea water, and the inter-relations of animal and plant communities. In both field and laboratory experiments fission products are useful but some problems require the use of artificially radioactive substances produced by other means. An outstanding example is the use of carbon 14 to study the efficiency of various steps in the food chain. Large quantities of this material are needed for field studies in restricted water bodies. Though the cost would be high, the value of the results would more than justify the expenditure.

CONCLUSIONS AND RECOMMENDATIONS

1. Tests of atomic weapons can be carried out over or in the sea in selected localities without serious loss to fisheries if the planning and execution of the tests is based on adequate knowledge of the biological regime. The same thing is true of experimental introduction of fission products into the sea for scientific and engineering purposes.

2. Within the foreseeable future the problem of disposal of atomic wastes from nuclear fission power plants will greatly overshadow the present problems posed by the dispersal of radioactive materials from weapon tests. It may be convenient and perhaps necessary to dispose of some of these industrial wastes in the oceans. Sufficient knowledge is not now available to predict the effects of such disposal on man's use of other resources of the sea.

3. We are confident that the necessary knowledge can be obtained through an adequate and long-range program of research on the physics, chemistry, and geology of the sea and on the biology of marine organisms. Such a program would involve both field and laboratory experiments with radioactive material as well as the use of other techniques for oceanographic research. Although some research is already underway, the level of effort is too low. Far more important, much of the present research is too short-range in character, directed towards *ad hoc* solutions of immediate engineering problems, and as a result produces limited knowledge rather than the broad understanding upon which lasting solutions can be based.

4. We recommend that in future weapons tests there should be a serious effort to obtain the maximum of purely scientific information about the ocean, the atmosphere, and marine organisms. This requires, in our opinion, the following steps: (1) In the planning stage committees of disinterested scientists should be consulted and their recommendations followed, (2) funds should be made available for scientific studies unrelated to the character of the weapons themselves, and (3) the recommended scientific program should be supported and carried out independently of the military program rather than on a "not to interfere" basis.

5. Ignorance and emotionalism characterize much of the discussion of the effects of large amounts of radioactivity on the oceans and the fisheries. Our present knowledge should be sufficient to dispel much of the over-confidence on the one hand and the fear on the other that have characterized discussion both within the Government and among the general public. In our opinion, benefits would result from a considerable relaxation of secrecy in a serious attempt to spread knowledge and understanding throughout the population.

6. Sea disposal of radioactive waste materials, if carried out in a limited, experimental, controlled fashion, can provide some of the information required to evaluate the possibilities of, and limitations on, this method of disposal. Very careful regulation and evaluation of such operations will, however, be required. We, therefore, recommend that a national agency, with adequate authority, financial support, and technical staff, regulate and maintain records of such disposal, and that continuing scientific and engineering studies be made of the resulting effects in the sea.

7. We recommend that a National Academy of Sciences-National Research Council committee on atomic radiation in relation to oceanography and fisheries be established on a continuing basis to collect and evaluate information and to plan and coordinate scientific research.

8. Studies of the ocean and the atmosphere are more costly in time than in money and time is already late to begin certain important studies. The problems involved cannot be attacked quickly or even in many cases, directly. The pollution problems of the past and present, though serious, are not irremediable. The atomic waste problem, if allowed to get out of hand, might result in a profound, irrecoverable loss. We, therefore, plead with all urgency for immediate intensification and redirection of scientific effort on a world-wide basis towards building the structure of understanding that will be necessary in the future. This structure cannot be completed in a few years; decades of effort will be necessary and mankind will be fortunate if the required knowledge is available at the time when the practical engineering problems have to be faced.

9. The world-girdling oceans cannot be separated into isolated parts. What happens at any one point in the sea ultimately affects the waters everywhere. Moreover, the oceans are international. No man and no nation can claim the exclusive ownership of the resources of the sea. The problem of the disposal of radioactive wastes, with its potential hazard to human use of marine resources, is thus an international one. In certain countries with small land areas and large populations, marine disposal of fission products may be essential to the economic development of atomic energy. We, therefore, recommend: (1) that cognizant international agencies formulate as soon as possible conventions for the safe disposal of atomic wastes at sea, based on existing scientific knowledge; and (2) that the nations be urged to collaborate in studies of the oceans and their contained organisms, with the objective of developing comparatively safe means of oceanic disposal of the very large quantities of radioactive wastes that may be expected in the future.

10. Because of the increasing radioactive contamination of the sea and the atmosphere, many of the necessary experiments will not be possible after another ten or twenty years. The recommended international scientific effort should be developed on an urgent basis.

11. The broader problems concerned with full utilization of the food and other resources of the sea for the benefit of mankind also require intensive international collaboration in the scientific use of radioactive material.

REPORT OF THE COMMITTEE ON THE EFFECTS OF ATOMIC RADIATION ON AGRICULTURE AND FOOD SUPPLIES

I. GENERAL

The Committee interpreted its task as requiring its members to survey the scientific aspects of that great sequence of events which precedes the delivery of food items to the ultimate consumer, and to do so from two separate viewpoints. These were (1) the beneficial effects that may result from the deliberate involvement of radiation of any sort with constructive intention, or what has been spoken of so frequently as the "peaceful uses of atomic energy," and (2) the harmful or disadvantageous effects of radiation of any sort due to nuclear warfare, to accidents involving atomic power plants, or even to a slowly rising background of radiation that conceivably may follow as a result of atomic technological developments in industry.

Public and private funds are currently being expended in the United States for research in agriculture and food processing at a rate in the vicinity of 300 million dollars annually. And undeterminable but not insignificant fraction of this considerable body of research involves radiation or radioisotopes. Members

of the Committee did not believe it to be incumbent upon them to defend or justify, to criticize or to challenge applications of atomic radiation to agriculture that have been developed or are under discussion. They did not wish to evaluate the programs of particular agencies or groups, but instead with judicial mind to examine the accomplishments and the potentialities, the implications and the limitations of radiation as related to the production and processing of agricultural products.

One broad conclusion is that there is not imminent any drastic change in *agricultural production* as a result of the application of radiation. However, radiation techniques provide new tools for research and may aid agricultural production by improving and enhancing the efficiency of production methods.

The Committee is strongly of the view that the applications of radiation will be of far greater immediate consequence to agricultural research than directly to agriculture, and that most of the benefits that may arise to agriculture, as manifest in the availability of an adequate and varied supply of wholesome food for man, wherever he may be, will come as a summation of many improvements, small and large, in materials, in plants and animals and in the technology of husbandry and processing developed through programs in agriculture and food processing research.

Changes therefore may be expected to come in a series of little steps, none of which in themselves may be of great impact, but which, through the years, are likely to be impressive in their total.

Another broad conclusion is that the slowly rising background of radiation caused by weapons testing in peacetime at the present rate is not likely to impair or interfere with food production. Levels of radiation considered tolerable by man are below those believed to have effects in plants or animals that would place food production in jeopardy. However, the high levels of radiation which might develop in small or large areas as a result of atomic or thermonuclear weapons in wartime, or from mishaps with nuclear power plants in peacetime could have catastrophic effects on agricultural production that might be of long duration, because of injury to personnel and animals, disruption of services, and contamination of soil, vegetation and water supplies.

II. TRACER STUDIES IN AGRICULTURAL RESEARCH

In the consideration of the beneficial effects of radiation the Committee endeavored, not wholly successfully, to separate in its thinking those benefits that may arise from additions to the pool of basic knowledge about plants and animals and their welfare, from those more direct effects that may specifically result from the exposure of plants, animals or agricultural products to radiation. Tracer studies in the biological sciences have already been enormously fruitful in aiding the elucidation of essential metabolic processes in plants and animals, and may be expected to be increasingly so as the number and diversity of such experiments increases. When there is knowledge and understanding of a process then comes the opportunity to control it for a desired end; in this way the art of agriculture is transformed to the science of agriculture.

They endeavored to make the separation mentioned above because of the conviction that there is nothing unique about radioisotopic studies as applied to agricultural research. Tracer techniques, however, frequently permit answers to be obtained to questions which seemed previously unanswerable by conventional experimentation. The involvement of isotopes puts a new dimension into metabolic studies, and areas, formerly dark, may now stand out in relief.

It is worthy of comment that many of the applied problems involved in the arts or technology of agriculture are as susceptible to study by procedures involving radioisotopes as are those more basic questions of plant and animal physiology or nutrition. Excellent examples of this type of employment of isotopes are to be found in work on the placement and recovery of phosphorous fertilizers in soils, the efficiency of various methods of application of insecticides, fungicides and herbicides, the determination of post-harvest residues of such chemicals, the extent of utilization of feed components by animals, etc. It is to be anticipated that there will be greatly increased use of tracer radioisotopes in the solution of such applied problems, and that the immediate dividends from such research may be considerable. Further, it is likely that new methods of employing isotopes advantageously will be developed; the ingenuity of investigators in this field should not be underestimated.

Because of the unanimity of their views as to the enormous potentialities of isotope tracers as a research tool in agricultural science and biology generally, the Committee gave some consideration as to whether there are limitations in

facilities for training or funds for specialized equipment for such studies. The consensus seemed to be that motivation for the use of such techniques must come from individual investigators themselves, that the necessary know-how is to be found in almost all research institutions, and that progress in agricultural research is not at the moment limited by inadequacies in dissemination of knowledge and techniques. There was, however, a feeling that much of the graduate training in this field is rather informal, that more universities might consider establishing courses in which the methodology, techniques and principles of this new and powerful science are expounded, and that there is an additional need for an advanced training program for specialists in radiochemistry and radiobiology who may be developers of new techniques or interpreters of new applications of potential value in agricultural research.

III. EFFECTS OF RADIATION ON CROP PRODUCTION

It is abundantly established that mutations can be induced in many plant species by exposure to x-radiation, gamma radiation and other forms of radiation. The changes which result are possibly due to chromosome deletions or abberations. There is some difference of opinion as to whether radiation-induced mutants intentionally obtained are qualitatively identical with those which occur spontaneously from naturally occurring mutagenic agents, but there is no doubt that their frequency is increased. Even so the mutation rate in most species is still very small, and furthermore most mutations are disadvantageous. The investigator seeking to exploit this phenomenon must expect to have to handle very large populations, and so far has been able to look only for desirable changes that are reflected in morphology or appearance and therefore can readily be seen, or for changes which can be recognized by some blanket method such as inoculating all irradiated plants with disease organisms in the hope of finding one or more exhibiting resistance to infection.

It is likely that characters at present unrecognized also undergo change and that there are unexplored potentialities for effecting improvement in quality that may alter the demand for the plant, or in physiological properties that may alter the relationships of the plant with its environment.

It would be a mistake to imply that this new development has greatly simplified the tasks of those involved in crop improvement. On the contrary, it has made them more complex, but, by extending the boundaries, offers many new possibilities. It is not to be expected that acceptable new agronomic varieties can be obtained by simple irradiation of present varieties, though this is possible if large enough populations are examined. In general, however, back-crossing and recombination are needed to add the new characteristic to a crop plant acceptable in other respects.

As yet relatively few new varieties of economic plants, developed from radiation-induced mutants, have actually been introduced and widely planted. These, however, do attest to the potentialities of the procedure. Much of the research effort in this field has properly been devoted to the investigation of techniques, to such vital questions as the determination of the particular stage of development at which radiation exposure may be most effective, and the comparative mutability of crop species. It appears that different species cannot be expected to respond in an identical manner. More perhaps is known about this aspect of corn genetics than of any other major crop plant.

Mutations in micro-organisms may similarly be induced by exposure to various types of radiation, though at considerably higher radiation levels than with crop plants. The changes induced have been shown to include the degree of virulence and host range of certain pathogenic fungi. The suggestion has repeatedly been made that the plant pathologist should examine this phenomenon so as to anticipate disease-resistance requirements in a breeding program. As yet, however, there have been no significant results along these lines. Considerable success has been achieved in the development of greatly enhanced antibiotic production by some molds through radiation-induced mutation and selection. Similar genetic changes in the case of other micro-organisms have produced information about the likelihood of genetic control of metabolic processes.

There is considerable evidence that bud mutations or somatic mutations can be induced by radiation, and that this phenomenon can be exploited in the development of new strains of crop plants that are normally propagated by cuttings and grafting. This may be of special value in the improvement of some such crops, but as yet there have been no striking accomplishments in this direction. Progress in such studies is however inevitably slow because of the

nature of the materials, the length of time necessary to recognize a desirable change, and to produce the stocks necessary for field evaluation.

Since the mutation rate of plants may be enhanced by radiation, presumably there is some possibility of the appearance of undesirable mutants in areas where the background radiation becomes higher than normal for any reason. This may be of some significance in connection with waste disposal practices or atomic accidents. There is, however, no evidence of such changes in areas containing radioactive springs or ores. This may be due to lack of intensive examination of the vegetation of such areas, and such surveys are to be encouraged. However, the likelihood of appearance of undesirable lines under radiation levels that would be tolerated on other grounds seems small.

There is no evidence that plant growth is stimulated or crop yields increased by exposure to low levels of radiation, despite earlier well-publicized claims to this effect. Radioactive fertilizers, used in a conventional manner, produce yield increments no greater than expected from ordinary fertilizers.

Plants accumulate nutrient elements present in the root zone in solution or absorbed onto soil colloids, but non-nutrient elements are not excluded and may similarly be taken up. The availability of radioisotopes has greatly improved the understanding of plant nutrition and soil-plant relationships, and may be expected to aid substantially in the improvement of cultural practices, as indicated earlier. Through the use of isotopes it has been demonstrated unequivocably that certain elements can enter the plant through the leaves. This is of some consequence in relation to fall-out. Radioisotopes of long life or high activity if deposited in fall-out from an atomic or thermonuclear incident are likely to be accumulated in crop plants by root uptake from the soil and entry through the foliage. Some of the products deposited may be initially quite insoluble, but may become soluble through weathering. Others, initially soluble, may be irreversibly fixed by many soils in a form not readily available to crops. It appears at present that Sr^{90} and I^{131} are the chief radioactive elements which are of concern in such circumstances. The subsequent use of such crops presents a great diversity of problems depending on the level of radioactivity, its nature and the specific use of the crop. The Committee was interested to learn that the Department of Agriculture is preparing for farmers some informational material relating to these problems.

The Committee desires to examine further the available information on the inter-actions of fall-out components with soil their entry and accumulation in crop plants in order to determine whether there is available the necessary basic information from which appropriate agronomic recommendations could be formulated for agricultural operations in areas that may have undergone any likely level of contamination.

IV. EFFECTS OF RADIATION ON ANIMAL PRODUCTION

Whereas it appears that crop improvement programs may be considerably aided by the availability of radiation-induced mutants that may have certain desirable characteristics capable of incorporation into an agronomically acceptable variety, currently available evidence does not suggest that a similar approach with animals would be so rewarding. This statement is made not from a belief that farm animals are inherently less responsive to radiation than plants but because physical differences of size, cost, generation time, etc., militate against extensive studies with animals, and act as obstacles that cannot readily be overcome. Probably only with poultry and to a lesser degree with swine would it be possible to handle large enough populations, and even here, if one extrapolates from the smaller laboratory animals, the chances of improvement seem slim. At present one such study, with chickens, is known to be underway.

Limited whole-body exposure studies with farm animals have primarily been carried out to investigate physiological and pathological changes, often with the intention of transferring the information by analogy to problems of responses in man. The sequence of changes induced in most farm animals by heavy radiation exposures has been well defined. There are one or two examples however of the use of radiation exposure as a research tool for inhibiting certain functions in animals. For example various functions in the oviduct of poultry can be blocked by proper radiation techniques thereby permitting a study of the contribution made by the parts of this organ.

Much of the work with radioisotopes in the animal field centers around problems of animal nutrition and metabolism, and substantial progress has been made both in the elucidation of fundamental problems of animal physiology as

well as in those of a more applied character, such as the utilization of feed constituents, and the incorporation in animal tissues of inorganic constituents of forages. The experimenters in this field at present encounter one serious difficulty, which in the case of the larger farm animals greatly limits the scale of activity. This is the problem of the salvage or disposal of animals after use in experiments involving radioisotopes or radiation exposure. Even in the case of short half-life isotopes and at tracer levels only, the animals cannot be marketed through the usual outlets. This problem is of course much more serious with dairy or beef cattle than with hogs or poultry because the cost to the program is so much greater. Moreover, this limitation tends to restrict undesirably the scale and scope of such experiments, with the result that the conclusions may be less surely established than if the numbers of animals used were larger.

It appeared to the Committee, therefore, that essential research on farm animals using radioisotopes or radiation is being discouraged by the high costs involved because animals must be destroyed at the termination of experiments. It recommends that a special committee be appointed to study this problem and to develop procedures and standards that, if followed and enforced, would adequately protect the consumer, but permit the marketing of animals that in experimentation have been brought into contact with radioactive substances or exposed to radiation.

The welfare of the livestock population is enhanced if troublesome insect pests can be controlled or eradicated. As mentioned earlier, insecticide studies have been greatly aided by the availability of radioisotopes as tracers, but in addition there may be certain opportunities for control of insect pests by taking advantage of radiation-vulnerable stages in their life cycles. Eradication of the screw worn fly from the southeastern United States is to be attempted, based on the virtual elimination of this fly from the island of Curacao by the release of males rendered sterile by radiation exposure. This technique may not be generally applicable to all insects pests.

V. RADIOISOTOPES IN AGRICULTURAL PRODUCTS AND FOODS

The Committee discussed in detail some of the difficult problems that may arise because of the presence of a radioisotope burden in agricultural products and foods higher than that "naturally occurring." The applicable legislation in this area is clouded with uncertainties, because the very possibility was not envisaged by those who enacted the laws and defined the responsibilities of the agencies that protect the public food supply. There are no permissible limits for radioisotopes in foods; any burden above the "natural" is regarded as undesirable. The current interpretation of the law places isotopes in the same category as poisonous additives. It is difficult, however, to be wholly consistent in this, inasmuch as the normal radioisotope burden varies considerably in different agricultural products, and in the same product from different locations. Moreover, the testing of atomic and nuclear weapons is placing in soil, water, and air, the world over, radioisotopes not formerly present, though at extremely low levels. Th "natural content" of foods now consumed by animals and man is not the same as in the pre-atomic age. Though extremely small, the increment is measurable, and inescapable.

It is to be anticipated that there will be in the years ahead a slowly rising background of radiation manifest in agricultural and food products by the presence of the isotopes of elements not previously found therein or of "unnatural" levels of radioactivity. Atomic warfare might greatly increase the rate of this development. As pointed out earlier in this report, radiostrontium is particularly the element which would cause concern in the latter event. Forage directly contaminated with fall-out, if consumed by farm animals soon after deposition might cause radiation injury from the presence of insoluble radioactive products. Strontium is metabolically similar to calcium and moves into bone and other calcium-accumulating tissues or fluids. Much is known of the relative behaviors of calcium and strontium but there appears to be no way of wholly preventing strontium retention. There is some evidence that poultry may "decontaminate" or "detoxify" themselves by reason of a continued dilution through transfer to eggshell. In meat animals certain tissues might be consumable if boned out, but such an expedient would be beyond the ordinary scope of meat inspection. Dairy products would contain radiostrontium for some considerable time after ingestion of strontium-containing forage. Moreover, all avail-

able feeds, in heavily contaminated aras, might contain significant levels of radiostrontium, perhaps for years.

At present it is not possible to say at what level a food, otherwise wholesome, becomes unwholesome or deleterious by reason of the presence of an unnatural burden of radioactivity. There is a great deficiency of requisite data on the long-term biological effects that may follow the ingestion of such foods by animals and man. Situations in which such information might be of great public importance are not inconceivable and possibly inevitable.

The Committee therefore urgently recommends that appropriate experimentation be immediately activated to provide specific information about possible total or cumulative biological effects that might follow the ingestion of such foods. It further urges that the planning of such experiments be broadly based, and that the development of the experimental designs and details of their subsequent execution be most carefully considered in order that the emerging data will be acceptable as a basis for the crucial decisions that ultimately will have to be taken, and directly of value to the regulatory agencies charged with the protection of the public interest.

VI. ENVIRONMENTAL CHANGES AND ECOLOGICAL STUDIES

In the decades ahead there is a strong possibility that the general background of radioactivity in agricultural areas will rise. Contributing to this would be fall-out, if weapons-testing continues, and wastes from nuclear power plants or isotope processing plants. As indicated in the report of another Committee every effort will have to be made to contain radioactive wastes. Atomic warfare, or accidents involving nuclear power sources could of course greatly augment the background and pose difficult problems of land-use for agricultural purposes. Limited ecological studies are in progress in the vicinity of certain A. E. C. installations, but it may be wise to consider this general problem somewhat more widely and to attempt to establish, through careful sampling, the present background in representative agricultural areas, and in their chief crop and livestock products.

Research activities might appropriately be carried out on areas near weapons test sites where substantially greater changes in background would be anticipated. The distribution in the environment, in the soil at various depths, in the vegetation, in the wildlife, in the streams, etc. would all be pertinent. The rate of accumulation in soil as affected by land use ought to be studied. Forested land, rangeland, rotation grassland, and plowland, irrigated and non-irrigated, may each present a different situation. It is possible that certain of the State Agricultural Experiment Stations might be in a position to undertake limited surveys of this type on areas likely to be under their control for some considerable time in the future.

The Committee recognized clearly that sustained monitoring and ecological research activities of this type are expensive and are not apt to be professionally rewarding to the individuals participating therein, because trends and conclusions would emerge only slowly. However, to be able to recognize changes in the levels of radioactivity in the environment and in products removed therefrom, and to follow movements in the system, may well be in the public interest from a long-range viewpoint.

VII. EFFECTS OF RADIATION ON PLANT OR ANIMAL PRODUCTS (FOOD PROCESSING)

A recent development in food technology, potentially of considerable and possibly dramatic significance, is the recognition of the fact that radiation can be used as a means of preserving certain foodstuffs or of lengthening shelf life, either unrefrigerated or refrigerated. The radiation source may be gamma rays or high energy electron beams. No radioactivity is induced in the irradiated material. Feeding experiments to date indicate that foods so irradiated will prove to be suitable and safe for consumption by man. Parasites in meat and meat products can be killed by exposure to penetrating radiation; and undesirable post-harvest changes in plant products, such as the sprouting of potatoes, can be delayed.

The prime objective in radiation processing is to destroy microorganisms, or so greatly to reduce the microbial population (radiation pasteurization) that spoilage is long delayed. To accomplish this, very heavy radiation exposures are necessary because microorganisms are much less sensitive to radiation than are animals and higher plants. The food processor is particularly attracted by

the fact that the radiation exposure can and should be carried out after packaging.

The acceptability of some radiation sterilized foods is open to doubt because of the development of off-flavors, and changes in odor or in the texture of the tissues. Much of the developmental work in this field however has been of a rather empirical nature, and it is possible that through research means may be found to repress some of these undesirable changes.

Although the feasibility of radiation sterilization has been amply demonstrated, the economics of the various processes have not yet been established. This development has largely been financed by the military with the Army Quartermaster Corps as the primary agency involved, but there has been a broad basis of cooperation in industry and elsewhere, with some technical guidance and evaluation by Advisory Committees of the National Academy of Sciences. Having in mind the magnitude and coherence of the current broad programs in this area the Committee was of the opinion that the potentialities of this use of radiation are being thoroughly explored, and that the interests of the food consumer will be adequately protected. At a later date the Committee expects to review particularly the evidence of wholesomeness and acceptability of irradiated foods.

VIII. COMMITTEE MEMBERSHIP

The names and institutional affiliations of members subscribing to this report are listed below. In their deliberations they were aided by Douglas M. Whittaker of the Rockefeller Institute and Charles I. Campbell of the staff of the National Academy of Sciences-National Research Council. As Consultants the Committee is indebted to A. J. Lehmann, Food and Drug Administration, Robert Somers, Meat Inspection Service, U. S. D. A., J. Wolff, Atomic Energy Commission.

Summary Report of the Committee on Disposal and Dispersal of Radioactive Wastes

INTRODUCTION

Experience in handling the waste disposal problems to date is mostly limited to conditions as they exist in the areas of the national atomic energy establishments. The determination of hazards from the disposal of wastes in these areas, most of which are in remote and somewhat isolated regions, involving relatively short periods of time, has to date revealed no deleterious effect on the public or its environment.

This does not provide, however, a completely adequate basis for projecting the magnitude of the hazard into the vastly expanded realm of industrial atomic power production. Not only does the problem itself take on new significance with the projected amount of wastes, but environmental factors which may lie dormant under conditions existing in the remote areas take on full blown importance when viewed under the more stringent requirement for highly populated areas.

Many such problems immediately come to the surface as a result of consideration of the long-term legal and insurance aspects. These problems reflect first of all a need for deeper understanding of the basic issues and for more refined measurements, and not merely for greater but still unknown factors of safety. Long-term responsibilities, moral, legal, and financial, stemming from the ownership of atomic wastes simply come into sharp focus when it is emphasized that the radioactive life of the wastes would probably exceed by several centuries the official life of the organization itself. Legal and insurance requirements, therefore, will undoubtedly have a great deal to do with the shaping of rigid administrative policies with respect to these long range aspects of the atomic waste disposal problem. It may be difficult to maintain an adequate balance between objectives which primarily must emphasize the legal requirements and those

which in the broad biological sense must establish the foundations for a truly preventive approach to this problem.

PRESENT STATUS OF PROBLEM

The following listing summarizes the conclusions regarding the status of waste dispersal and disposal operations:

1. The safe handling and ultimate disposal of radioactive wastes is an important technical, economic and administrative aspect of the nuclear energy industry. Waste operations must be thoroughly integrated with all other phases of nuclear energy operation.
2. From a technological standpoint the highly radioactive wastes resulting from the processing of reactor fuels constitute the bulk of the problem. To date essentially none of those wastes has been disposed of, i. e., returned to the environment. Tank storage is presently utilized as an interim answer to this problem.
3. Wastes resulting from normal reactor operations are an important consideration, but technically represent a problem for which solutions are generally available.
4. Research and development have indicated possible feasible systems for ultimate controlled disposal of highly radioactive wastes, but considerably more work is required to bring these systems to the point of economic operating reality.
5. Major technical and economic considerations underlying the waste problem are:
   a. Characteristics of nuclear fuels and chemical (or other) processing associated with them.
   b. Separation of specific isotopes from the wastes and use of these materials to economic advantages.
   c. The proper selection of the site for nuclear facilities—especially reactor and fuel processing plants.
   d. The detailed quantitative evaluation of the environment in order to assess its capacity to receive radioactive materials without creating deleterious effects on the environment.
   e. Systems for the physical handling and transportation of highly radioactive materials.
6. Major policy and administrative considerations relevant to the regulation of the waste problem are:
   a. The establishment, perhaps through private enterprise, of suitable waste disposal services.
   b. The regulation and control of waste disposal practices through existing and traditional state, interstate and local channels where feasible.
   c. Continuation and strengthening of established practices in relations with the public and its agencies.

RELATION TO NUCLEAR INDUSTRY GROWTH

Based on the best estimates available (which vary over rather wide ranges) and, to a substantial extent on technical judgment, the indications are that the principal source of fission products from nuclear reactors in the next decade will arise from the generation of electricity at nuclear powered central stations. On the basis of present developments, the second most important source probably will be reactors for naval service. Compared with these, other sources are comparatively small and amount to substantially less than the uncertainty in the estimates of the principal uses.

By 1965 the average rate of reactor heat release is estimated to be about 11,000,000 kilowatts. Naval service will account probably for 20 percent of this output in 1965. This rate of heat release will result in the production of somewhat over 10 kilograms of fission products per day in 1965.

In addition, the presence of radioactive wastes in quantity will have a profound effect on certain non-nuclear industries which may be damaged by air or water contaminated with radioactive wastes. Numerous wet-processing industries are likely to be detrimentally affected by radioactive wastes even in trace concentrations. Among this vulnerable group are those requiring water of the highest purity, such as for the manufacture of photographic film. Other industries which should be alerted to the problem are pharmaceutical manufacturers and food processing companies. It is not possible, at this time, to enumerate with assurance the industrial processes which can be completely

eliminated as subjects of this potential hazard, without the assembly of extensive research and statistical data applicable to specific operations.

RELATION TO FUEL PROCESSING AND TYPES OF REACTORS

Neither the type of fuel nor the length of irradiation time greatly influence the accumulated total radioactivity of fission products. Atfer approximately three years decay the residual radioactivity is essentially the same for various irradiation times, assuming constant heat generation during the irradiation period.

Essentially all of the radioactive material from fuel separations processes must be kept from the environs to maintain human exposures within maximum permissible limits. An important problem which possibly limits storage volume is the rate of heat removal from the containers. After solvent extraction wastes are concentrated by supplied heat to about 2000 gallons per ton of irradiated uranium, the heat of radioactive decay will continue the concentration to 100–500 gallons per ton. Practical heat removal mechanisms may require that more concentrated waste produced by other separations processes be diluted to the same volume range. More concentrated fluid wastes also need stronger, less economical containers. The volumes of stored waste accumulated by 1980 are estimated at 20 x 10^7 gallons, by 1990 at 60 x 10^7 gallons and by 2000 at 240 x 10^7 gallons.

The future possibility of high burn-up of reactor fuels might ultimately result in a situation where processing may be unwarranted. This would not change accumulation of fission products, but would have a profound effect on waste storage and disposal considerations. Similarly, the development of non-aqueous chemical processing methods would be important in modifying the waste management problem.

ISOTOPES PROBLEMS

The technical and administrative problems associated with the transport, use and disposal of radioactive materials in medicine, biology, and industry will undoubtedly grow in complexity and quantity as the demand for the use of these radioactive materials increases. The expanding demand is already apparent in the rapidly increasing number of individual isotope users as evidenced by the expansion of the isotope distribution program. The program for the distribution of reactor-produced radioisotopes is nearing one decade, having been initiated on August 2, 1946. During this period more than 100,000 shipments of radioisotopes have been made from AEC facilities to some 3,200 institutions throughout the United States. These materials are being applied in science, agriculture, medicine and industry. The Oak Ridge National Laboratory, the principal radioisotope production facility in the United States, has shipped approximately 130,000 curies to date.

All indices of radioisotope utilization reveal continued rapid growth. A look at the last three years of the program shows a growth in the number of using institutions from 1,400 to 3,200. This is an increase of approximately 125%. There has been a 100% increase in annual numbers of shipments made since January 1, 1953. The principal growth during the period has been in the industrial use of radioisotopes.

However, of even greater significance in connection with environmental and hazard control problems is the ever increasing desire for larger and larger individual sources of radioactivity. Requirements for intense radiation sources are obviously at their earliest stages. Such uses as food and pharmaceutical sterilization, promotion of chemical reaction, and other yet unknown applications will undoubtedly result in a much more extensive use of mobile and more widespread sources of intense radiation.

Increased use, especially of highly active materials and the increase in the production of by-product materials at widely scattered geographical locations will result in ever increasing new technical and especially administrative problems in both the transport of the material and the disposal of the wastes, in order to protect the environment against normal and potential emergency hazards.

Compliance with existing transportation regulations present few significant problems in the shipment of by-product material even through certain specific limitations exist. However, consideration should be given to a complete critical review of existing ICC, Civil Air, Coast Guard and Postal regulations to bring them in line with current requirements and radiation safety knowledge.

The radiological health and safety record in the nation-wide use of radioisotopes is excellent. Incidents which have come to the Atomic Energy Commission attention involving significant overexposure of personnel are exceedingly small; fewer than 10. In large measure this may be attributed to active educational efforts in radiological protection through a field advisory service to isotope users and through effective and practical licensing practices.

At present activity levels of use of radioisotopes and with the wide dispersal of users substantial environment health problems do not exist due to waste disposal or other practices resulting in the introduction of radioisotopes into the environment.

ITEMS REQUIRING FURTHER STUDY

The following listing summarizes conclusions in this area:

1. Geophysical and geochemical aspects of ultimate disposal of highly radioactive wastes.
2. Site selection for various nuclear facilities, particularly chemical processing plants and their location with respect to suitable waste disposal areas.
3. Transportation of highly radioactive materials.
4. Relationship of introduction and development of nuclear facilities to basic public health, social and economic situations extant or resulting from such development.

PROBLEMS OF ACCIDENTAL HAZARDS

The following conclusions in respect to the consequences of accidents involving radioactive materials appear warranted:

1. The problems of waste disposal could be international in character and must be solved technically so that the total environment is maintained at a low level of radioactivity in order that accidents that are bound to occur will not be disastrous.
2. The type of accident that could result in a catastrophic spread of radioactive materials is the complete vaporization of the core of a reactor and its release to the surroundings. The probability of a catastrophic accident with a properly designed nuclear reactor is extremely small.
3. Reactor waste processing plants or storage facilities offer a greater hazard on a long-term basis than any single reactor.
4. Accidents in handling, transport, and chemical separation of radioactive materials, while locally severe, should not affect a wide public area and, in all cases, the contaminated areas can be cleaned up.
5. The probability of accidents in handling radioactive isotopes and low-level radioactive materials is similar to that in handling other types of lethal substances.
6. Use of nuclear reactors to drive ships appears feasible from a consideration of the consequences of possible accidents provided uranium-233 and plutonium are kept to a minimum. The technology of the use of nuclear reactors to drive locomotives and commercial airplanes has not developed to the point where the committee can form a judgment as to the consequences of possible accidents.
7. Development of improved methods to limit the volumes of wastes produced in nuclear power reactors is justified from the viewpoint of the hazards due to possible accidents.
8. Continuous and vigorous appraisal of reactor and fuel processing plants design and operation and waste storage will be required in all nations using atomic energy in order to keep the radioactivity level of the world environment at tolerable levels.
9. Improved safety devices for control of transients in nuclear reactors should continue to be vigorously developed.
10. Further tests are required of reactors to evaluate their ability safety to withstand power excursions which may occur as a result of unusual operating circumstances.
11. Until such time as advances in the technology of reactors lessen potentially hazards substantially, sealed buildings properly designed, constructed, and tested should be required for all nuclear reactors to be built in or near populated areas.
12. All operations involving radioactive materials in sufficient amounts to create possible health hazards should be supervised by trained and responsible people.

FALL-OUT CONSIDERATIONS

It is apparent that as of the present time the dispersal of radioactive material resulting from weapons testing has not been an environmental contaminant of substantial public health significance. However, because of various unknown factors regarding distribution and ultimate fate of this material, plus the potentials of possible wider spread and more frequent weapons testing it is also apparent that the subject in all of its aspects merits meticulous and continuing attention. The problem of fall-out is one of international significance and should be studied and evaluated on that basis, perhaps looking forward to international cooperation in control.

THE NATIONAL ACADEMY OF SCIENCES—NATIONAL RESEARCH COUNCIL

The National Academy of Sciences—National Research Council is a private non-profit organization of scientists, dedicated to the furtherance of science and to its use for the general welfare.

The Academy itself was established in 1863 under a Congressional charter signed by President Lincoln. Empowered to provide for all activities appropriate to academies of science, it was also required by its charter to act as an adviser to the Federal Government in scientific matters. This provision accounts for the close ties that have always existed between the Academy and the Government, although the Academy is not a governmental agency.

The National Research Council was established by the Academy in 1916, at the request of President Wilson, to enable scientists generally to associate their efforts with those of the limited membership of the Academy in service to the nation, to society, and to science at home and abroad. Members of the National Research Council receive their appointments from the President of the Academy. They include representatives nominated by the major scientific and technical societies, representatives of the Federal Government, and a number of members-at-large. More than 3000 of the foremost scientists of the country cooperate in the work of the Academy-Research Council through service on its many boards and committees in the various fields of the natural sciences, including physics, astronomy, mathematics, chemistry, geology, engineering, biology, agriculture, the medical sciences, psychology, and anthropology.

Receiving funds from both public and private sources by contribution, grant, or contract, the Academy and its Research Council thus work to stimulate research and its applications, to survey the broad possibilities of science, to promote effective utilization of the scientific and technical resources of the country, to serve the Government, and to further the general interests of science.

EXCERPTS FROM PATHOLOGIC EFFECTS OF ATOMIC RADIATION, STUDY BY THE NATIONAL ACADEMY OF SCIENCES, NATIONAL RESEARCH COUNCIL

APPENDIX I

REPORT OF THE SUBCOMMITTEE ON ACUTE AND LONG TERM HEMATOLOGICAL EFFECTS OF ATOMIC RADIATION

Eugene P. Cronkite, Brookhaven National Laboratory, Chairman

ACUTE AND LONG TERM HEMATOLOGICAL EFFECTS

On January 7 and 8, 1956, the Subcommittee met at the National Academy of Sciences in Washington, D. C. with all members present. A preliminary report was written by Drs. Bond and Cronkite and distributed to Subcommittee members. The comments of the members have been incorporated into this report.

INTRODUCTORY COMMENTS BY THE CHAIRMAN

Mankind has always lived in an environment suffused with radioactivity from natural and unavoidable sources such as radioactive minerals and cosmic rays. Natural radioactivity varies greatly in degree throughout the world. Intensities tend to be much lower at sea level and on most small islands, with the exception of Baltic islands, throughout the world. At high altitudes cosmic ray activity increases significantly. Similarly natural radioactivity from minerals increases significantly in some mines, and in the water supplies of some areas. For example, water in the Joliet area in Illinois contains relatively large quantities of radium and its daughter products. Since the discovery of x-rays by Konrad Roentgen and natural radioisotopes by Becquerel and the Curies, there has been a steady increase in the amounts of radiation to which segments of mankind are being exposed. With the development of nuclear weapons and the spread of atomic energy by industrial activities, the levels of world wide radiation will unquestionably continue to increase.

At the present time there is confidence that the increment to the naturally existing radioactivity is but a small fraction of that believed to exist prior to the testing of atomic weapons and the presently developed atomic energy industry. However, when one specifies the diverse sources of radiation to which large numbers of mankind are being exposed, it is quite evident that serious concern must be felt by physicians and scientists for the possible influence of such radiation upon individuals, selected groups, and whole populations. In the course of the deliberation of this panel attention was called to the existence of the following types of exposure to radiation to which human beings were exposed, voluntarily and involuntarily.

1. Natural sources
2. World wide low-level fallout
3. Roentgenographic surveys of large segments of the population for tuberculosis and cancer
4. Dental x-rays
5. Industrial fluoroscopy and radiography
6. Fluoroscopy of infants
7. Fluoroscopy for shoe fitting
8. Diagnostic x-rays
9. Medical and scientific use of tracers in human beings
10. Therapeutic use of radioisotopes and x-ray
11. Tracer radioisotopes in agriculture and industry
12. Research and power reactors
13. Ionizing radiations for food sterilization
14. Experimental accelerators

During the early years when the diagnostic and therapuetic uses of x-ray were being developed, heavy and repeated exposure to physicians, physicists, nurses, and technicians resulted in serious injuries. Historically, the occurrence of leukemia and aplastic anemia as late sequelae of exposure to x-ray and radioactive substances was well documented in the medical literature prior to 1937. Presumably Madame Curie died from an aplastic anemia. In recent years, while great care has been taken to avoid heavy radiation exposure, there is little knowledge on the hazards of repeated smaller does, especially in regard to late effects on the blood forming organs.

The record of the atomic energy development, which involved the handling of large amounts of dangerously radioactive material is an example of the effectiveness of the controlled environment.

Dose dependence and correlation of other effects with hematologic effects

In order to set the acute and chronic hermopoietic effects of radiation into the proper perspective with regard to overall radiation effects, the whole body radiation syndromes as a function of dose of radiation are summarized:

After very large doses of radiation delivered in a short time, a typical clinical syndrome is produced in animals. On the basis of observed symptomatology, it has been useful to name this symptom complex the central nerous syndrome (CNS). In animals, doses in excess of many thousands of r, are necessary to produce this complex. There are species variations. The "threshold" for this syndrome in man is not known and this syndrome has not been observed in man. Symptoms referable to the nervous system and GI tract appear promptly. Death may occur "under the beam" or within a few hours. In laboratory animals this syndrome invariably results in death either promptly, or later as a result of the next clinical syndrome which results in death at a later time. If the nervous symptom complex subsides, or if the dose has been smaller (in the region of 900–5,000 r for laboratory animals; dose for man not known), a symptom complex termed the gastrointestinal syndrome (GIS) appears. Nausea and vomiting appear shortly after exposure. Diarrhea and tenesmus become severe. The GI symptoms may be intractable or may subside for a variable period. Fluid and electrolyte loss from the GI tract progressively produce dehydration and eventual vascular collapse, and death that may occur during the 1st and 2nd weeks. This picture was observed in the Japanese casualties and has been well studied in laboratory animals. Death from this syndrome has been prevented experimentally in some dogs by adequate fluid and electrolyte replacement; in addition spontaneous recovery may occur after the lower doses in this range. However, the survivors then experienced another symptom complex that may result in death. It is this third symptom complex characterized by signs and symptoms referable to bone marrow depression which characterizes the lethal dose range.[1] By custom, the mortality from this syndrome has been tabulated as of 30 days after explosure. There are reasons, to be discussed later, why a 30 day tabulation may be too short for human beings.

A fourth phase of deaths was observed during the 2nd and 3rd months after exposure in the Japanese casualties in which in some instances the causes of death were not clear; however, pancytopenic sequelae were still present. Hemopoietic recovery was in progress but defects in proliferation and maturation were observed in the pathologic sections of marrow. Following the third month, deaths are infrequent and it becomes increasingly difficult to ascribe deaths to the effects of radiation since phenomena observed are those which may result in death in any non-irradiated population. In some instances cause of death was uncertain although pancsytopenia was prominent.

There is evidence that large single doses, or repeated small doses of radiation can produce diverse neoplasia, genetic defects, and shortened life span in select controlled *animal* populations. However, attempts to ascribe a specific role to irradiation in neoplasia in *human* populations becomes an exceptionally complex biometric study because of the increasing contamination of the atmosphere by industry with potential carcinogens, and the introduction and widespread use of an array of clinically useful drugs, whose long term effects in man are imperfectly understood, but which in some cases have produced severe blood dyscrasias. Accordingly, in all of the discussions on the long term effects of single doses of radiation on *man*, and the effect of repeated or low level exposure, one must be especially cognizant of the fact that the "effects" are *deduced* by statistical *correlations*, and cannot be proved by controlled experimentation, nor can other causative factors be eliminated. In this era of awakened public interest to the hazards of radiation, it is especially important that preoccupation with the hazards of ionizing radiation does not becloud the searching mind of the scientist or the responsible citizen to the presence of other hazards of equal importance. This is not an attempt to minimize the hazards of ionizing radiation with respect to the development of blood dyscrasias and other late effects. It is most

[1] Sublethal refers to the lower doses of radiation that will produce no deaths within a given period of time, usually taken as 30 days in animals. The lethal range extends from the threshold dose at which only rare deaths occur in this time interval, to the level at which virtually all exposed will die (the LD 1 to LD 99 range). Doses above the LD 99 level are termed supralethal. In all ranges, however, ultimate longevity is reduced to some degree.

important to bear in mind that the incidence of bone marrow failure[3] and leukemia has increased significantly in the United States in groups in whom there is no known overexposure to ionizing radiations. Today no informed physician believes that exposure to ionizing radiation has either a beneficial or stimulating effect on the blood.

In the course of the deliberation of this Subcommittee, attention was focused upon the known effects of nuclear explosions, the immediate and long term effects of single exposures from all causes, and the long term effects of intermittent and continuous explosure to radiation of diverse types. In the latter category, the Subcommittee felt that a reasoned judgment could not be made because of the paucity of realistic quantitative data on the degree of exposure.

ACUTE HEMATOLOGICAL RESPONSE TO SINGLE DOSES OF PENETRATING RADIATION

Although the available sources of hematological data on human beings exposed to total body external radiation have serious limitations, they were considered to be reasonably consistent among themselves to allow characterization of the time course of change in peripheral elements following exposure. The sources of data included the reports of the Japanese exposed to immediate radiation from atomic weapons, the account of the human beings accidentally exposed to fallout radiations at the Pacific Proving Grounds in March, 1954, the reports of human beings exposed to reactor accidents in the laboratory, and data on patients with incurable neoplastic disease exposed to therapeutic total body irradiation. The pattern of response of the peripheral blood elements changes with increasing radiation dose. In the following description, changes are divided into those that occur in the sublethal range, and those that occur in the lethal range (doses that result in some mortality within 60 days of exposure). This division is arbitrary, since the patterns of change merge imperceptibly, and each category covers a range of doses and thus degree of effect. When the dose is increased from sublethal levels to lethal levels, the lag period between exposure and depression is progressively shortened.

Response after sublethal doses

The *neutrophil* count shows an initial use in the first 12 to 24 hours followed by a sharp drop, to or below, the pre-exposure level. The count then fluctuates around or slightly below the pre-exposure level until the 3d or 4th week, following which definite depression is observed. The time of maximum depression occurs during the 5th or 6th week or even later, and is followed by a gradual return to pre-exposure levels. Complete recovery may require several months or more.

The drop in *lymphocytes* is early and profound. Little or no evidence of recovery in the high sublethal range may be apparent several months after exposure, and return to former levels may not occur for months or years. The total white count parallels closely the change in neutrophil count.

The *platelet* count shows little or no change over the first three weeks following exposure. At approximately the end of the 3rd week the platelet count falls. The time of maximum depression is remarkably constant at sublethal dose levels, and occurs on the 28th to the 32nd day of post-exposure.

No trend in eosinophile, basophile, or monocyte counts can be definitely ascertained. This may result in part from the larger errors inherent in counts of these cells. In the absence of hemorrhage, the hematocrit may show slight depression. This effect is probably due to a combination of inhibition of erythropoiesis and shortened life span of the red cell.

Response after doses in the lethal range

The *neutrophil* count may rise during the first two days following exposure. The count then falls steadily to reach values below 1,000/mm^3 by the 5th to the 10th post-exposure day, depending on dose. In survivors, recovery begins during the 5th week, but many not be complete for several months.

The *lymphocyte* count drops to vanishing levels within 12 to 24 hours of exposure; recovery is not apparent for several weeks; and it may not be complete for several months, or for a year. The total white count parallels the neutrophil count.

---

[3] Synonymous with aplastic anemia, refactory anemia, hypoplastic anemia. Aplastic anemia has been observed to terminate in leukemia. The occurrence of aplastic anemia after use of diverse drugs is common clinical knowledge.

The *platelet* count in the lethal range, in marked contrast to that at lower doses, may drop precipitously, starting approximately on the 4th day, and platelets may virtually disappear from the peripheral blood by the 10th day.

Changes in the eosinophiles, basophiles, and monocytes counts cannot be characterized definitely at this time. The hematocrit [3] is not appreciably affected until hemorrhage occurs, severe gross external or occult internal bleeding may occur as early as the 9th day, depending primarily on the time at which the platelet count reaches dangerously low levels. This may occur from the second to the fifth week, with peak incidence in the 4th week in the low and mid-lethal dose ranges. The degree of response as a function of dose varies for the several blood elements. The platelet and lymphocyte counts are affected by very small doses of radiation, and are reduced to minimal levels before the lethal dose range is reached. The neutrophil count, however, does not reach minimal values until the lethal range is reached.

Comparison of man and other mammals

The time course of changes in the leucocyte and platelet counts in human beings is definitely different from that observed in lower animals. In man, severe depression of these elements occurs later, and recovery is more delayed. Similarly, the time of deaths in man resulting principally from hematological depression differs from that of laboratory animals. In most laboratory species, essentially all animals alive on the 30th post-exposure day will remain alive for several months, although the life span is shortened. In man, however, the peak incidence of death from marrow depression occurs during the 4th and 5th post-exposure week (Hiroshima and Nagasaki data). Thus an LD 50, 30 day consideration is inadequate to characterize the acute lethal dose response of man, and an LD 50, 60 days would be preferable.[4] The extensive serial blood counts obtained in human beings exposed to fallout gamma radiations were relied on heavily in characterizing the hematological responses of human beings exposed to external radiation. Admittedly the dose rate with fallout was much lower than with prompt radiation and may have reduced the effectiveness somewhat. These individuals received, in addition to gamma radiations, beta radiations of the skin, and probably a minimal degree of internal contamination. It was the consensus of the Subcommittee that neither the beta lesions nor the low level of internal contamination significantly contributed to the pattern of change observed. This view was supported by the general agreement of these data with other less extensive data on human beings who did not receive additional skin lesions or internal contamination; and the lack of correlation between the severity of hematological change and the extent of beta lesions in those exposed to fallout radiation. The reservation was held, however, that data are inadequate to establish this view with certainty, and that synergistic effects cannot be ruled out.

Mortality and morbidity from whole-body radiation

The pan-hemopoietic depression contributes in large measure to morbidity and mortality following total body irradiation. In the sub-lethal and low lethal ranges, the response observed is consistent with other clinical pancytopenic states. Neutrophil depression increases the susceptibility to infection and platelet depression contributes to the bleeding tendency. Correction or treatment of these defects during the first few weeks may permit survival in some individuals who might otherwise have succumbed. The concept of total body x-radiation as primarily a pancytopenic state, while useful, is probably an oversimplification, particularly in low and high lethal ranges.

Susceptibility to infection is well established and the pathogenesis may well involve interference with specific immune mechanisms, phagocytosis, and migration of leukocytes in addition to simple neutrophil depression.

Susceptibility to bleeding is well correlated with platelet depression. However, additional factors may be involved such as lipid antithromboplastins (Tocantins) or disturbances in the β lipoprotein transport mechanism (Nickson and Bane).

---

[3] Admittedly the hematocrit can be misleading since it represents both changes in plasma volume and red cell mass. However, in general decreases in hematocrit represent a diminution in red cell mass for one reason or another (loss, hemolysis, or no new production).

[4] The reservation must be made here that the exposed Japanese population were heterogeneous with respect to age, sex, physical condition and degree of added trauma from burns or blast. The extent to which these factors affected survival time has not been determined. In studies on laboratory animals the converse is true—homogeneous populations are studied.

In some instances, the latter changes are similar to changes induced by heparin administration to rabbits. The relation of these alterations to the bleeding tendency has not been established. It was the consensus that frank heparinemia is not a contributing cause of bleeding.

After *higher doses*, death ensues even if hemorrhage and infection are corrected. Germ free rats die at dose levels moderately higher than the lethal dose for rats in the natural state. These animals die later with severe hemorrhage and anemia. At dose levels in excess of the LD 100, 60 day level, individuals die within the first week presumably from fluid imbalance and vascular collapse correlated with marked damage to the intestinal epithelium. It is clear that at all dose levels, poorly known and little understood biochemical changes[5] occur which may contribute to mortality in the exposed individual. Our knowledge is inadequate to determine at the present time to what extent such biochemical changes may prove lethal in themselves even when infection and hemorrhage can be treated adequately.

Lethal dose for man

No data are available to allow adequate characterization of the LD 50 value for man. The degree of hematological depression observed in patients receiving total body x-radiation indicates that the current estimate of 450 r is a reasonable estimate for x-radiation as employed in the clinic. A recent re-evaluation of the data from Hiroshima and Nagasaki indicated a value higher than this for immediate gamma radiation from the bomb. Geometrical and depth-dose considerations can be interpreted to indicate that the LD 50 for man exposed to immediate gamma radiation and fallout gamma radiation from the atomic bomb may be lower than this figure. A large degree of uncertainty exists in both approaches, and more biological and physical data are required to settle the issue. The situation is complex, and it became evident that it is not possible to extrapolate with confidence from one condition of radiation exposure to another, or from animal data to man.

Threshold dose for detectible effects

There appears to be no threshold[6] dose for changes in the peripheral platelet count and possibily for other elements of the blood. Changes at very low dose levels, however, can be detected only in a relatively large population. Nothing is known about subtle changes in the blood forming organs at dose levels so small that changes in the blood picture cannot be detected.

Diagnosis of radiation exposure and its severity

The diagnosis of exposure to radiation and its severity is made on the basis of the history and physical and laboratory examinations, as with any disease. Available estimates of air roentgen dose received obtained by physical means should be considered in evaluating the degree of exposure, but should never in themselves be taken as an index for disposition or treatment since *tissue dose* and *distribution* of absorbed energy ultimately determines effect not dose in air. Any degree of radiation exposure should be avoided if possible. If exposure is necessary under emergency conditions, severe hematological depression may be expected at doses of 100 r or more measured in air, from immediate radiation from the bomb or from the gamma radiation from fallout material. With human exposure a wide spectrum of ages and of state of health is likely to be involved. Thus it is not possible to predict acccurately the severity of response that might be expected for a population exposed at various dose levels. There is evidence from the human beings exposed to fallout radiation that children may be more severely affected than are young adults. Whether this is due to inherently greater sensitivity or to an increased depth dose due to smaller size is not known. From animal data, it has been postulated that elderly individuals may be more seriously affected than young adults.

Therapy of radiation injury

Recommendations for therapy are given for 1) conditions where exposed individuals can be carefully and individually handled because they are limited in number and adequate facilities exist for taking care of them, and 2) ex-

---

[5] Apparently decreased respiratory quotient (RQ) in animals, increased excretion of amino acids in irradiated human beings, etc.

[6] The threshold concept may be incorrect since inability to detect effects at lower doses may only be a manifestation of inadequate criteria for effect. For practical purposes a threshold might be classified as that dose where statistically sifinificant differences are detected. For many effects this may necessitate extremely large samples.

posures at the catastrophic level where adequate medical observation and care are impossible. In the first category, of cardinal importance in therapy is careful observation, good nursing care, and treatment on an individual basis of any condition that may arise. Antibiotics in general should not be given prophylactically, and should be administered only if infectious processes develop that would be treated with antibiotics in the absence of radiation. Prophylactic use of antibiotics may be considered if the neutrophil count drops below 1,000/mm^3. Prophylactic use of antibiotics may be considered particularly where severe wounds or other complications may be present. If antibiotics are used, they should be given in large doses and the broad-spectrum drugs should be employed. Fluids should be given as indicated clinically. Blood should not be given prophylactically, but only as indicated from clinical and laboratory findings. Fresh whole blood by direct silicone multiple syringes without anticoagulant or collected in plastic bags or platelet transfusions may be of some value in controlling purpura and other hemorrhagic manifestations. The use of drugs without clear indication is discouraged because of their unknown and possibly harmful effects on the irradiated individual whose metabolism is deranged. Parenteral administration of drugs should be held to a minimum because of the added trauma in an individual susceptible to purpura and infection. At present there are no specific prophylactic or therapeutic agents[7] that should be stock-piled for us ein the hematological depression and the resulting disease state following exposure to total body irradiation.

Under catastrophic conditions it of course will not be possible to adhere to the above regimen. The principles of therapy remain the same, except that here there is a much better potential case for widespread and empirical antibiotic dispensation, particularly to individuals in which burns, mechanical wounds or other added trauma exist.

LONG TERM EFFECTS ON THE BLOOD OF A SINGLE EXPOSURE TO IONIZING RADIATION

The best single source of information on this subject is the Japanese survivors exposed at Hiroshima and Nagasaki in August, 1945. Of necessity, data on the immediate radiation effects are fragmentary and data on the exposed individuals between the 16th week and the 2nd year are not available. In 1954 a statistical analysis of the hematological data obtained by studies on Hiroshima survivors and a control population, carried out from 1950–1953 (ABCC Program ME SS) showed that there was no evidence for an increase in leukopenia, leukocytosis or anemia in the exposed as compared to the control population. During this period several cases of aplastic anemia were encountered among the Nagasaki survivors. However, it cannot be definitely stated that these cases were due to atomic radiation. Up to late 1953, no cases of aplastic anemia had been found in the Hiroshima survivors. It should be noted that "aplastic" anemia is not an uncommon blood dyscrasia in the Japanese.

Incidence of leukemia

In contrast, an increased incidence of leukemia among survivors has been clearly established. It has long been known that repeated or single doses of radiation could increase the incidence of leukemia under controlled experimental conditions in laboratory animals. Accordingly, an intensive investigation of the incidence of leukemia in the irradiated survivors in Hiroshima has been carried out by the ABCC. This study is continuing and a statistical analysis, based on the verified cases of leukemia occurring in the Hiroshima survivors, establishes beyond reasonable doubt that the incidence of leukemia was significantly increased in exposed individuals.

The following graphs and tables are based on the 1947–1953 incidence of leukemia in Japan and have been supplied by the Committee on Atomic Casualties of the National Research Council.

---

[7] Antibiotics of great value in the therapy of infection in the exposed individual are not considered here as specific drugs. Such prophylactic agents known to this panel such as sulfhydryl compounds, hypoxia inducing drugs, spleen or bone marrow preparations, etc., claimed or shown to favorably modify acute radiation injury in animals, have no place as yet in the treatment of human radiation injury.

Leukemia in exposed persons—Number and rate by presence of radiation symptoms and distance from hypocenter

Distance from hypocenter—meters	Hiroshima population [1]			Number of cases of leukemia [2]			Incidence		
	SRC [3]	NRC [4]	Total	SRC	NRC	Total	SRC	NRC	Total
Under 1,000	750	450	1,200	14	2	16	246.2	58.6	175.8

YEAR OF DEATH
Note: 10 patients still alive. Their deaths may form another peak in next year or two.

The preceding tables and graphs clearly indicate that the incidence of leukemia increases with the dose of radiation. The incidence of radiation complaints at 2000 to 2500 meters is open to question since the dose received at these distances was between 8 and 35 r according to the best source of information.[3] It is noteworthy that radiation complaints are based on late interrogation and not on medical records by competent observers at the time of the bombing and as such are prone to subjective error in memory by the individuals interrogated. At closer distances this possible error is probably negligible because of the unquestioned and recorded histories of radiation injury. The peak incidence of onset appears to have been passed in 1951; however, scattered cases are still being observed, but relationship to confirmed previous exposure to radiation injury is obscure.

Since precise data on the radiation doses received at Hiroshima and Nagasaki have not been made available to the ABCC it is not possible to set a "Dose threshold" for induction of leukemia in man by whole body radiation. Such information is vital to the future welfare of human beings who may be forced to live in contaminated areas. In addition, with the growing belief that there may not be threshold levels for radiation effects it becomes absolutely essential to obtain the most reliable estimate of the exposure wherever osbervable effects have been detected.

In Japanese atom bomb survivors the leukemias have been predominantly myeloid. However, Dr. Furth of the committee emphasizes that radiation induced *lymphatic* leukemias in Europeans have been observed. In this connection it is of interest that lymphatic leukemia is a rarity in Japan suggesting that radiation is prone to induce the type of leukemia that might occur spontaneously.

Hematologic changes preceding development of obvious leukemia

In the course of studies on Japanese atomic bomb survivors, observations on hematologic changes preceding development of overt chronic myelogenous leukemia were made in a number of cases. In routine surveys, blood studies revealed evidence of a generalized proliferative effort by the bone marrow, many months before obvious evidence of leukemia. These manifestations were the presence of a small per cent of myelocytes and metamyelocytes, and a very striking increase in absolute numbers of basophils, in the peripheral blood. These changes were accompanied by increaed numbers of platelets and occasional normoblasts. Beginning in November, 1952, biochemical studies on the separated leukocytes demonstrated that in these early pre-clinical cases of leukemia, the polymorphonuclear leukocytes contained very little alkaline phosphatase. These alkaline phosphatase values were similar to those reported by Valentine et al. for neutrophiles in well established cases of chronic myelogenous leukemia.

Subsequent studies in chronic myelogenous leukemia, employing histo-chemical as well as biochemical methods, have shown that 2 per cent or less of segmented polys contain even small amounts of alkaline phosphatase. In contrast, in other conditions with increased polymorphonuclear leukocytes such as infection and myeloid metaplasia, the alkaline phosphatase values are high and practically all segmented neutrophiles contain large amounts of alkaline phosphatase.

It has been postulated that the leukemic cell is deficient and in the precursor stage of development of leukemia, two populations of cells are present with the leukemic type increasing in number until a typical leukemic blood picture is evident. It has been the experience of some of the Subcommittee members that cases of "bone marrow failure" may terminate in leukemia.

EFFECTS OF REPEATED LOW LEVEL EXPOSURE

Increasing numbers of human beings are exposed to repeated does of radiation frequently at very low dose levels. Thus in industry and in AEC installations, in radiologists and radiological technicians, public health surveys and particularly those using fluoroscopy, and in repeated roentgenograms in medical and dental diagnosis, large populations are exposed to radiation at levels well in excess of background.

[3] The Effects of Atomic Weapons, U. S. Government Printing Office, Washington, D. C., 1950.

There are several studies on radiologists and radiological technicians, indicating that statistically the blood counts of such individuals may be altered. Similarly from the vast number of counts on individuals exposed to low level radiations at AEC installations, there is evidence that the so-called maximum permissible dose may result in statistical alteration in the blood count. The possible significance of these small changes is not clear. The slight decrease in neutrophiles or lymphocytes count has little or no significance in itself. It would appear that its significance in relation to the later development of leukemia or other disease that shortens life span should be investigated. Recommendations to this effect are given below. Data are available on the hematological effects of exposure to radiation up to 10 times background. The drinking water of prisoners at Joliet prison in Illinois contain 20 times the radium content of the drinking water of neighboring communities. Extensive study has failed to detect differences ascribable to the increased radium content of the drinking water. In the course of radiotherapy for relatively benign conditions, it seems clear that serious late effects can result from a single exposure or a series of exposures to x- or isotopic radiations. Thus thyroid cancer has resulted in children given x-radiation for thymic enlargement. Similarly, leukemia has been reported in individuals receiving repeated x-radiation therapy for spondylitis, and in patients receiving repeated I–131 for thyroid cancer.

USEFULNESS OF HEMATOLOGIC STUDIES IN CONTROL OF RADIATION INJURY

A large effort at great expense was made by the AEC during the development of atomic energy to determine if routine hematologic studies would detect low level exposure to radiation. It was the consensus that frequent routine studies on personnel exposed to low levels of radiation have a limited value that does not justify the expense. Physical control of the environment by radiation monitoring is an effective means of maintaining a safe environment, and nothing is gained by widespread hematologic studies on personnel. However, it would not be wise to dispense completely with hematologic studies since it is important to have pre-exposure levels in the individuals who may be exposed to radiation such as with those accidentally exposed to fallout radiation. Had base line studies been available relative depression and recovery time as a function of dose could have been more precisely determined. Accordingly it is believed that periodic, perhaps annual hematologic studies should continue on limited groups of individuals who run a greater risk of accidental over-exposure. Certainly, all individuals who have been exposed so accidentally at dose levels of 25 r or more of essentially whole body radiation (single exposure) should have periodic systematic studies to determine the degree of hematologic depression and the recovery rate. These individuals should remain away from an environment where further overexposure is likely until the dose received has been amortized at the rate of 0.3 r/week. The latter is suggested because clinical radiation therapy experience indicates that individuals who have been exposed previously as a result of local therapy or whole body exposure show greater hematologic depression following further whole body radiation. A more fruitful field of hematologic study in relation to chronic radiation exposure would appear to be the periodic study of phosphatase content of the neutrophils and number of basophils, on limited populations, who are known to be exposed chronically, such as radiologists, urologists, orthopedists, x-ray technicians, and dentists.

RECOMMENDATIONS FOR RESEARCH

A. Recommendations With Respect to the Acute Hematological Response of Human Beings to Radiation

(1) The Japanese data from Hiroshima and Nagasaki bombings should be further analyzed in respect to:

(a) Duration of depression of leukocytes as a function of distance and shielding (dose).

(b) Leukocyte counts at various intervals in relation to ultimate survival.

(c) Survival time as a function of distance and shielding (dose), and of age.

(d) The degree of initial blood count depression in relation to the later development of leukemia and other late disease.

(2) Additional and intensive studies should be initiated on human beings receiving radiation to the whole body or large portions of the body in the therapy of malignant disease. Particular attention should be given to the time course of

peripheral blood counts for several weeks following exposure to different doses, and the nature of the clotting defect.[9]

(3) Initiate studies on the cause of death in animals in which death from hemorrhage and infection have been prevented. This refers to deaths within the first few weeks, as opposed to the much later deaths from nephritis, neoplasia, etc.

(4) Although nothing of practical value is now available for the specific therapy of acute radiation injury, it is urged that further research be pursued on the fundamental defects produced by ionizing radiation on mammalian systems. *Medical experience has shown that rational therapy is only developed when the basic physiologic defects are understood.* With this in mind further research is needed. However, it would be unfair to the public to imply that effective therapy can be expected in the near future or indeed that overwhelming doses are ever likely to yield to therapy.

B. Recommendations With Respect to Long Term Effects of a Single Exposure to Ionizing Radiation

(1) Periodic hematologic surveys should be performed on the Marshallese and Americans exposed to fallout radiation in March, 1954. Careful study for cytological changes mentioned above, especially basophilocytosis and immature leukocytes, and routine bistochemical studies for alkaline phosphatase (using peripheral blood smears and either Gomori's Cobalt technique or the azo dye method) should be carried out. In suspicious cases, biochemical determinations for alkaline phosphatase on separated leukocytes should be done. In view of the long "latent period", studies for many years after exposure if not for life, are essential.

(2) The cytologic and histochemical-biochemical studies might well be employed in surveys of radiologists and other chronically exposed groups.

(3) The present concepts of leukemoid reactions and myeloid metaplasia, and the relationship of these disorders to leukemia are obscure. Further studies on the enzyme and metabolic activities of leukocytes in these disorders may lead to a better understanding of radiation effects on myeloid cells and the role of irradiation in leukemogenesis.

(4) It is generally recognized that routine hematologic studies of potentially exposed individuals are wasteful and unproductive. However, studies on select groups by routine and newer techniques are highly desirable, e. g., radiologists, physicist.

(5) It was the consensus that it would be desirable to know the incidence of leukemia in WW I soldiers who were exposed significantly to mustard gas.

(6) Pediatricians have fluoroscoped newborn babies, and a considerable dose of whole body radiation may have been received. A long term follow-up on these exposed children is needed.

C. Recommendations With Respect to Effects of Repeated Low Level Exposure

(1) Since there are geographical locations in which the known radiation intensities vary considerably, it is felt that the incidence of leukemia should be established in:

(a) Island populations (low background except Baltic Islands)

(b) Andes (high background)

(c) Prison and civil population in Joliet (radium content in water higher than normal)

(2) It was the consensus that a ceaseless search should be continuously made for other harmful agents in the atmosphere and our modern diet. It is genuinely felt that preoccupation with radiation may obscure other equally hazardous factors in man's environment.

CONCLUSIONS

At the commencement of the deliberations there was some question in the minds of the Subcommittee as to the objectives and the reasons for establishing it. However, in the course of the discussions it became apparent that in addition to the confusion in the minds of the public there also exists some large gaps in knowledge essential for the understanding and quantification of radiation hazards in the world of today let alone the world of the future. The immediate effects of direct exposure to high intensity radiation are well documented and the relation

[9] One member of the panel reactivated the heparinemia concept of radiation hemorrhage by describing the cessation of bleeding in an irradiated individual with thrombopenia following injection of protamine, an antiheparin agent.

of dose to effect is known with some degree of confidence, even though certain hiatuses exist that are listed in the general discussion and recommendations. In the realm of chronic exposure it was recognized that the unavoidable background level of radiation was known to vary with seasons of the year, geographical location, and altitude above sea level. However, world-wide levels do not seem to be known with sufficient accuracy to determine when a rise in atmospheric level of radiation is definitely occurring. Since there is little quantitative information on the relation of dose to effect under conditions where harmful effects were observed it becomes vital to ascertain natural levels of radioactivity and to try to establish the level of atmospheric radioactivity at which detectable chronic effects might conceivably occur. However, with all of the recommendations contained in this report, it is believed that a "crash-type" research program to obtain needed information is not indicated.

Bibliography—Radiation Effects on Blood and Blood-Forming Tissues of Man—1900—March 1956

Prepared by Marjorie Comstock, Research Library, Brookhaven National Laboratory

INTRODUCTION

The literature was searched for references relating to the effects of radiation on blood and blood-forming tissues of man. In this bibliography, radiation includes radiation from neutrons, alpha, beta, gamma rays, A-bomb, x-rays and internally deposited radioisotopes. References relating to ultraviolet, infra-red, microwaves, thermal radiation and visible light have been omitted.

The following sources were checked:—

Chemical Abstracts (CA) v. 1 (1907)–v. 48 (1954)
Chemische Zentralblatt (CZ) 1897–1906
Current List of Medical Literature (CLML) v. 19 (1950)–v. 29 (March 1956)
Nuclear Science Abstracts (NSA) v. 1 (1948)–v. 10 (March 15, 1956)
Quarterly Cumulative Index Medicus (QCIM) v. 1 (1927)–v. 53 (1953)
Quarterly Cumulative Index to Current Medical Literature (QCI) v. 1 (1916)–v. 12 (1926)
Library Files

In addition to the above sources, Zentralblatt für die gesamte Radiologie was also used to check references. References are available in the Research Library unless otherwise indicated. The secondary source, abbreviated as above in parenthesis, is given when possible for references not available at the Laboratory. Journals have been abbreviated according to the Chemical Abstracts list as far as possible. In some cases where the authors initials were known, they have been added in parenthesis although they did not appear either in the original article or in the abstract.

An effort has been made to check references for pertinency. This could not be done for some of the earlier references due to the lack of abstract journals covering the subject. It was necessary to rely solely on the title for many of these entries.

Every effort has been made to make this bibliography complete. However, there is no way of knowing whether or not this has been accomplished.

TOXICITY OF INTERNAL EMITTERS

The Subcommittee on Toxicity of Internal Emitters met on January 10 and 11 at Argonne National Laboratory. They discussed the subject from many aspects including a certain amount of classified literature which is not referred to in this report but which it is believed would not alter the conclusions. The agenda were not followed literally in order to promote free discussion, so this report contains a somewhat rearranged version of the discussion.

Statement of the Problem.—The question of safe working exposure levels for industrial and laboratory practice has been intensively studied and is presented in the National Bureau of Standards Handbook 52. (Several members of the Subcommittee agreed that while this represents the best body of data and opinion. it is not the last word, in the matters of use of the biological half-life for all isotopes and the high relative biological effectiveness of alpha rays, in particular. It is thought that the Handbook will probably undergo some changes and that these changes will in general be in the direction of withdrawing a little from the conservatism with which the figures were originally reached.)

Important matters of public concern are: (1) radio-elements (that is, fission or activation products) close to a ground burst of an atomic bomb; (2) more remote fallout; (3) gradual world-wide fallout, especially of strontium-90; (4) consequences of a nuclear reactor accident near a populated center. Other prob-

lems of course exist, but most of the answers will be encompassed in a consideration of these.

The categories of data to be considered include: (1) acute and sub-acute radioelement toxicity and its relation to external radiation damage in an area of heavy contamination; (2) nature and dosage requirements of chronic radiation damage from various radio-elements; (3) physical, ecological, and physiological conditions determining absorption of radio-elements; (4) metabolic handling of radio-elements after their absorption; (5) therapy.

Problems requiring special consideration were: (6) realistic appraisal of absorption from the gut and retention in and absorption from lung; (7) influence of particulate or "hot spot" irradiation, especially in lung and skeleton; and (8) permissible dosage to a large "innocent" population in relation to that to industrially exposed persons for which the present levels are drawn.

The nuclides considered in particular fall in the following groups:

(1) Radium, strontium, barium, calcium; readily absorbed with long-term retention in the skeleton.

(2) Iodine; readily absorbed, of short physical half-life but highly concentrated in the thyroid.

(3) The rare earths, yttrium, and plutonium and other actinides; nearly insoluble and poorly absorbed.

(4) Ruthenium; absorbability ambiguous due to multiplicity of chemical forms.

(5) Cesium; in all probability readily absorbable.

(6) Activation products, various and unpredictable, generally considered unimportant.

Of the above, strontium and iodine received the most consideration. The background of natural radioactivity was also given consideration because of its relation to large population exposure.

Fallout Conditions.—The larger particulates fall out first and smaller ones at a greater distance, for obvious physical reasons. Fission products are plated on the larger, near-in particulates, probably reducing their absorbability. The strontium isotopes, since they exist for a short period after fission as krypton isotopes, escape to some extent from entrapment in larger particles; accordingly, they appear in a smaller ratio than their fission yield in the near fallout and are somewhat enriched at a distance: also, they appear as smaller particles and are more readily absorbed. Rabbits analyzed in Nevada showed a higher skeletal concentration at 133 miles from the test than at greater or less distances.

A detailed study of the effects of the fallout from the thermonuclear explosion of March 1, 1954 on the Marshall Island inhabitants, which is to be published soon (see Cronkite et al. in the references) discusses the body burden from material absorbed into the human body under the conditions of exposure encountered there. Estimates based on excretion rates indicate an initial body burden of Sr^{89} of about the permissible amount, while the I^{131} retained is estimated to have delivered a thyroid dose of the order of 100 rep. Other radioelements (including Ca^{45} and fissile material) are relatively negligible. The opinion of the Subcommittee, that products of neutron activation would be unimportant beside fission product activities, is borne out by this. Data in Table I, from a Japanese publication, are essentially confirmatory, and include autopsy findings which bear out the inferences from measurements on human excreta. It is noted that these low levels of internal contamination existed in persons who received a significant fraction of the human external lethal dose from gamma radiation.

The chemical nature of fallout elements has apparently not been well enough studied to yield many useful inferences about absorbability.

Acute Toxicity.—This would be encountered in pure form only in the event of absorption of specific products. In exposure to large amounts of mixed fission products or by inhalation in a fission cloud, external gamma and beta radiation would be expected to be by far the predominant source of injury.

Acute toxicity from a variety of isotopes generally manifests itself as acute radiation sickness. In combination, bone-seeking and colloidal isotopes act synergistically, due in large part to the fact that spleen and bone marrow are both irradiated in the combined treatment. Feeding of insoluble beta emitters may cause intestinal death, but only after enormous doses, because of the rapidity of their passage through the intestinal tract and because in those places where they remain the longest most of the energy is absorbed by the fecal material which is present there.

Subacute changes depend on the distribution of the element in the body. Hematologic effects are, of course, seen where bone marrow or total body irradiation predominate, and it might be mentioned that strontium-89 or 90, although they produce marked hematologic changes and acute radiation syndrome, produce no or almost no leukemia in mice. The doses required for these subacute changes may be an order of magnitude below those giving acute toxic symptoms. Premature aging, greying of hair, retinal changes, reduced blood volume, and changes in the blood colloids have been observed in dogs given radium and plutonium but not with strontium-90. No explanation of this is available, but these are animals run in parallel experiments. Arterial calcification also occurs in rats after they are given radium in subacute doses, but has not been seen with other nuclides.

Chronic Toxicity: Site of Injury.—It may be stated generally that the more important nuclides will act quite differently depending on the route of administration and their absorbability through the lung or gut, it being generally assumed that these will run parallel.

Materials such as yttrium, the rare earths, and plutonium are very little absorbed by either route, and the predominant hazard will therefore be to the lung. Those with experience in this agree on a general picture of the fate of inhaled, optimal-size particles (those most likely to gain access to the alveoli) in the range of 0.1 to 2.0 microns in diameter. About 25 per cent of this material is exhaled at once; 50 per cent is trapped in the bronchi and is carried up and swallowed within a short time (the half-time being about 9 hours); 25 per cent is deposited in the alveoli and, of this, three-fifths reaches the gut, by way of respiratory passages, leaving a 10 per cent deposition in the lungs. That fraction disappears in cases of inhaled radium sulfate in human cases which have been followed, with a half-time between 100 and 200 days, a very small amount being absorbed.

Absorption of these insoluble materials from the intestine is taken as 0.003 per cent. That was a consensus and obviously may not refer to all possible circumstances. Speaking generally, 10^{-4} is about the highest figure for intestinal absorption which would be found under most conditions. There appears, however, to be an exception in very young animals. Mice before 16 days of age absorb 2 to 3 per cent of plutonium administered either as the citrate by stomach tube or in milk from a plutonium-poisoned animal. From milk it continues to be absorbed in the ratio of 1 : 300 by young adult mice, although when it is present as the citrate it is not. Parenthetically, one suspects that this reflects an ability of the very young animal to absorb particulate material from the intestinal tract, for example, the milk factor. No data are available on other species so far as is known. Citrate does not promote absorption of plutonium in post-suckling animals but versene does.

Soluble materials are presumed to be absorbed both from alveoli and intestinal tract. Thus the route of entry becomes a matter of indifference. Absorption of specific elements will be discussed later.

As to whether any insoluble materials may be handled by plants in such a way as to promote their absorption, there is no positive information. They are generally not taken up by plants as well as by animals. It is reported, however, that for some reason hickory concentrates yttrium from the soil.

Effects on the Lung.—One microgram of plutonium (or 0.06 microcuries) introduced into the mouse lung as an "optimal" aerosol has proved toxic after a few months resulting in bronchial metaplasia, cellular infiltrations, and fibrosis, and carcinomas appeared after a year. The retained amount at that time has gone down to about one-twentieth of the dose administered, which is about what one would infer from the calculations stated above. Ruthenium administered in a similar way also produces pathologic changes, but data are not sufficient to indicate effective dose comparisons. It may be added that fibrotic changes occur in the human lung after 2,000 r of x-ray and rather regularly after 3,000 r. The Subcommittee on the respiratory tract headed by Dr. Wager has reported in greater detail on this topic.

Ruthenium.—The chloride of ruthenium is absorbed from the rat intestine to the extent of 3 per cent. This value is probably higher than for most of the chemical forms, except of course the tetroxide vapor which, if it were encountered (which is unlikely) would be well absorbed from the lung; this has been shown experimentally.

After absorption of ruthenium the chronic effects would most likely be in the skeleton, based on tracer work and some medium level toxicity work. While

ruthenium was found in animals after the Australian test, it is generally considered to be much less important than strontium.

Cesium.—The gamma ray of the cesium isotope 137 has been seen in normal individuals in the last year but in an amount of radioactivity far below that of body potassium. It was encountered as a deformation in the gamma spectrum of total body potassium and radium. No additional information is available, except that it appears to be somewhat variable and it my be correlated with the intake of milk, which apparently is, relatively speaking, a fairly rich source of radioactive cesium.

Activation Products.—Calcium was mentioned as a component of the Bikini ash, but toxicologically speaking would be a very minor contaminant of strontium. Activation of usual environmental elements would also yield corresponding minor amounts of insoluble material (rare earths and silicon) plus P^{32} and Na^{24}. It was reported that $Zinc^{65}$ was formed in high concentration in muscles of post-test Pacific fish, and it is recognized that other unexpected nuclides might turn up under specialized conditions.

The Alkaline Earths.—Strontium has quitely properly received major attention. It is a bone-seeker like the others of the series, and there is ample experimental evidence of its carcinogenicity in both masses 89 and 90. Since the best available human data regarding absorption and toxicity are from radium cases, this occupies first attention.

Metabolism.—Human radium retention in the age range 20 to 35, based on a 24-year follow-up, is described approximately by a power function of time with an exponent near —0.5; that is, retention varies as the inverse square root of time, being about 50 percent of the injected dose at the end of one day and following this function thereafter.

It may be remarked that indeed the retention of most absorbed materials of whatever nature can best be described by a power function unless one wants to construct a series of exponentials, although it may actually be a series of many exponentials. In all instances that have been carefully studied, even that of the retention of tritium oxide in the form of water, several exponentials exist. The rare earths and actinides show a much less steep slope than the alkaline earths.

There is also a species difference; the dog has a slope of —0.2 to —0.3, depending on age, which makes a great deal of difference in the accumulated dose in this animal.

Integrating this function in man, the cumulative radiation dose, assumed after a very brief period to be limited to the skeleton, goes up as the square root of time, and the rate of loss by excretion relative to the amount retained (specific loss), varies inversely with time. This gives one a way of determining when an exposure took place. It has been pointed out that this function gives a quantitative picture very different from that assuming an exponential half-life (which based on loss by chronic patients, where the loss is very low after 20 years, becomes very long).

It is clear, if this expression is correct, that throughout a human lifetime a man would accumulate little more than 100 days' intake. Observations on adolescent boys indicate that the accumulation to age 17 represents about 40 days' intake.

Evidence now bein accumulated in at least two clinics indicate that strontium-85, which is given because it is less toxic than the beta emitting isotopes, is handled by men in a nearly identical manner to radium. The initial loss varies considerably with age, being least in the younger individuals.

Toxicity.—The best available data on radium toxicity brought to our attention deal with a series of patients that received known amounts of pure radium chloride 24 years ago and were followed. The assumed minimum burden producing serious disease after this period has been taken as 1 microgram, but this has been questioned because of the fact that other preparations were in many cases contaminated with meso-thorium and, perhaps more seriously, with radiothorium. One bone tumor has appeared in one of these patients having 3 micrograms pure radium. The patient with the lowest burden in the series, that is, 0.4 microgram, shows diffuse minimal changes by x-ray, whereas other patients at higher doses from 0.6 to 1.0 microgram do not show detectable changes at this time. It can be assumed that the belief that the lowest effective burden is 1.0 microgram of pure radium is probably not in error by more than a factor of 2 from the standpoint of effects at 20 to 25 years.
